Statistics compiled from case fatality reports indicate that mortality in *Legionella* pneumonia is mainly influenced by the choice of antimicrobial therapy and by the previous state of health of the patient. The mortality rate is lowest for those who were previously healthy and who received erythromycin (about 5% mortality) and highest for patients who were immunocompromised and who did not receive erythromycin (about 80% mortality) [346]. The importance of accurate microbiological diagnosis or appropriate empiricism is illustrated by the observation that correct treatment lowers the mortality in immunocompetent patients from 25% to 7% and in immunocompromised patients from 80% to 25% [330]. When data recording the efficacy of different antibiotics are pooled, the overall mortalities with the use of erythromycin and tetracycline are comparable at 5–10% but for inappropriate antibiotics, including ampicillin, other penicillins, cephalosporins and aminoglycosides, mortality is high at 22–34% [337]. The crude mortality rate in a group of 84 patients sufficiently unwell to be admitted to an intensive care unit in Barcelona was 30% [347].

### Complications

Numerous complications have been described in association with *Legionella* pneumonia. These have often taken the form of individual case reports of rare associations and have been well reviewed [323,348].

Intrathoracic complications include respiratory failure, which may occur in 20–40% of cases so that ventilatory mechanical support may become necessary [121,330]. The prognosis in such cases is by no means hopeless [349]. Pleural effusions may occur but empyema is uncommon [350], as is cavitation [351].

Extrapulmonary legionellosis is rare and may occur as a result of bacteraemia. Cardiac involvement with pericarditis, myocarditis and prosthetic valve endocarditis have all been described [285,352,353], possibly as a result of nosocomial sternotomy wound infection with contaminated water, in which case there may be no evidence of pneumonia. Neurological sequelae may include confusion, memory impairment, cerebellar ataxia and peripheral neuropathy including Guillain-Barré syndrome [354,355]. Other extrathoracic complications have included pancreatitis and cellulitis [285]. Renal failure is usually due to associated hypotension in severe infections but interstitial nephritis [356], glomerulonephritis [357] and myoglobinuria [358] have also been reported.

### Prevention

At present, prevention of *Legionella* infections is limited to the identification of the sources where epidemics or case clustering have occurred. Expert advice should be sought when a point source of infection is suggested by the close temporal and spatial association of two or more cases [359]. In many such small clusters no source is in fact positively identified [290]. Hot water supplies are usually decontaminated by hyperchlorination, or by superheating water supplies to 70–80°C, and by the removal of rubber washers from shower fittings [360–362]. When cooling towers in large buildings have been shown to be the source, they are either shut down, modified or the water that they use treated with appropriate biocides [309].

### Pneumonia caused by species other than *Legionella pneumophila*

Over 40 different species of *Legionella* have been identified environmentally and a number of these may cause pneumonia. However, such infection is uncommon and when it does arise the host is not infrequently on immunosuppressive therapy [363–366]. The non-*pneumophila* species detected most frequently in these circumstances is *L. micdadei* (previously known as the Pittsburgh pneumonia agent). A number of *L. micdadei* pneumonia reports describe a more nodular pulmonary infiltrate than seen in

*L. pneumophila* pneumonia, the appearance having been likened to that of septic pulmonary emboli. *L. bozemanii* also tends to occur in immunocompromised patients and this species also seems to have a propensity towards progression and cavitation despite treatment with a macrolide, so that combined treatment including rifampicin is appropriate [367]. Other species may cause pneumonia infrequently [368–372]. Although good data on antimicrobial responsiveness is lacking, cases should probably be managed as for *Legionella pneumophila*.

### ***Mycoplasma pneumonia***

Mycoplasmas are the smallest free-living organisms [373]. They are quite unlike viruses and are able to grow and multiply extracellularly on artificial media, probably dividing by binary fission. They are nearest in their behaviour to bacteria but differ principally from these by their lack of a cell wall, being bounded by a deformable membrane, a characteristic that has resulted in their inclusion in a class of organism known as mollicute which means 'soft skinned'. Ten subgroups of human mycoplasmas are described and until recently only one, *Mycoplasma pneumoniae*, was known to cause respiratory infection in humans. *M. pneumoniae* is an important respiratory pathogen in the community [374], mainly affecting children and younger adults in whom it may produce pharyngitis, tracheobronchitis and, in a minority of cases, pneumonia. This is usually relatively mild but nevertheless accounts for a significant number of hospital admissions, occasional cases of which have been fatal.

The first mycoplasma to be isolated was obtained from cattle with 'pleuropneumonia' in 1898 [375] but the isolation of *M. pneumoniae* in humans had to wait until 1962 [376]. In the mean time it had been recognized that 'atypical pneumonia' could occur in humans in the absence of any recognizable pathogenic cause [377]. During the Second World War and subsequently, a relatively mild form of 'recruit pneumonia' was noticed to afflict troops in camps and barracks, and Eaton was able to pass on pneumonia to experimental animals from the filtered nasal washings of human cases, indicating a small pathogen that was termed the 'Eaton agent'. This agent was later grown on agar, identified as a mycoplasma and renamed *M. pneumoniae* [376,378].

There are a number of more recent publications indicating that some genital mycoplasmas may cause systemic disease outside the urogenital tract. One such organism is *M. hominis*, which has been isolated from lung tissue in young Australian Aboriginal adult males dying of pneumonia [379].

### ***Incidence***

Reported estimates of the relative incidence of *Mycoplasma pneumoniae* are bound to vary according to the nature of

the population surveyed and the diagnostic approach in individual studies. A multicentre British Thoracic Society study of patients with community-acquired pneumonia admitted to hospital found evidence of *M. pneumoniae* infection in 18% of 453 adult cases [281]. Individual hospital series have reported that *M. pneumoniae* constituted from 2% of 124 microbiologically confirmed cases over 1 year [167] to 14% of 210 cases, in whom infective agents were detected in 103 patients, over 3 years [165]. In the latter series, *M. pneumoniae* infection accounted for 25% of cases under the age of 50 years. This incidence of *Mycoplasma pneumoniae* was found to be higher than in other series, possibly because of two extended UK epidemics of *M. pneumoniae* infection that occurred during the period of the study [165]. The organism has accounted for about 4% of cases of community-acquired pneumonia requiring hospital admission in North American series [373,380], but it has been noted that in selected groups such as military personnel it may account for up to 44% of all cases of pneumonia [381]. *M. pneumoniae* was found to be the second commonest agent (after *Strep. pneumoniae*) causing hospital admission with pneumonia in young adult US military personnel over a 10-year period [382]. A large community survey in Seattle found that 15% of cases of pneumonia were caused by *M. pneumoniae* but also that it was a mild infection, only 2% of these patients requiring hospital admission [374]. Although predominantly affecting younger age groups, *M. pneumoniae* also causes pneumonia in old people. A large prospective study of community-acquired pneumonia admitted to hospital in Nova Scotia found evidence of *M. pneumoniae* infection in 4.9% of 1300 cases; of these 64 cases, only six occurred in patients aged 65 years or older [383].

### ***Epidemiology***

Sporadic cases of *Mycoplasma pneumoniae* occur in the population throughout the year [384]. Epidemics in the community at large tend to be prolonged rather than sharp, being spread over many months, peaks in incidence occurring every 4–5 years (Fig. 13.12), this being the case worldwide [373,385]. It may become relatively more common in the later summer months due at least partly to a decline in other causes of pneumonia such as pneumococcal infection. The organism is spread by droplet aerosol [386,387] and the infection is not highly contagious, transmission depending upon relatively close contact such as might occur between pupils at school and thence between family members in the home [388,389]. Localized epidemics of *Mycoplasma* infection may sometimes occur when large numbers of susceptible individuals are in relatively close contact, as is the case in schools or military establishments [388,390]. Shedding declines within a few days of the onset of the illness but may continue at a low level for weeks unless cut short by appropriate antibiotic therapy [391,392]. The chance of developing clinical infec-

**Fig. 13.12** Four-weekly reports of *Mycoplasma pneumoniae* infections in England and Wales showing prolonged pattern of epidemics spread over many months with cyclical peaks in incidence occurring every 3–5 years. (Data courtesy of the Communicable Diseases Surveillance Centre of the Public Health Laboratory Service.)

tion is reduced by pre-existing immunity, which is associated with the presence of circulating antibodies to the organism [373], so that attack rates within the family range from approximately 60–70% for children to 20–50% for adults [388]. Such infection need not manifest itself clinically as pneumonia. The duration of immunity is unknown and second infections have been recorded but are probably unusual [393,394]. Infection with *M. pneumoniae* may occur in immunocompromised individuals [395].

### Pathology

Respiratory disease in *M. pneumoniae* infection occurs as a result of the growth of the organism on the surface of respiratory epithelial cells, to which attachment may occur via a terminal receptor. Extrapulmonary spread of the organism is rare and disease at distant sites probably occurs as a result of immunological phenomena, circulating immune complexes having been detected in *M. pneumoniae* infection [396]. Fortunately few cases of *Mycoplasma pneumoniae* come to postmortem examination, and those that do may show pulmonary oedema and intra-alveolar haemorrhage with patchy areas of consolidation. Microscopic examination suggests that the primary process is bronchitis and bronchiolitis, with the presence of intraluminal neutrophils and macrophages and a submucosal and peribronchial infiltrate containing inflammatory cells with a predominance of lymphocytes and plasma cells. Progression to produce patchy or more confluent pneumonic changes, with diffuse alveolar destruction, hyaline membrane formation and fibrosis, may occur [397–399]. Postmortem diagnosis may be established from lung tissue using an *M. pneumoniae* DNA probe [399]. Ciliary motility may be impaired in common with other lower respiratory tract infections [400].

### Clinical features

Although *M. pneumoniae* may be an important cause of infection throughout life, it most commonly affects children aged 5–15 years in whom symptoms of coryza and

tracheobronchitis are the rule [401,402]. Pneumonic illness may occur in this age group but is usually mild and seldom requires hospital admission. Infection tends to be more serious when it affects older children and adults under the age of 50 years, in whom it is one of the more common pathogens identified as a cause of community-acquired pneumonia [165,402]. The incubation period is 2–3 weeks [403], after which clinical illness comes on gradually over the space of 2–4 days, with malaise, headache, myalgia and pyrexia. A sore throat and coryza are sometimes present. The cough may be dry at first, becoming productive of small amounts of mucoid or mucopurulent sputum sometimes flecked with blood. There may be substernal discomfort on coughing suggestive of tracheitis. Fever is usually sustained for several days unless modified by appropriate antibiotics or antipyretics, but rigors are unusual as is pleuritic pain. Patients may be prostrated but are seldom severely ill in the sense of being tachypnoeic or cyanosed. Cough, malaise and tiredness may persist for over a month. Examination of the chest may reveal crackles or wheezes over an affected area and there may or may not be local signs of consolidation. Bullous myringitis (painful haemorrhagic blisters on the ear-drum and external auditory canal) is said to occur in 5% of cases. Generalized lymphadenopathy and splenomegaly are occasionally elicited. There is a wide variety of other non-respiratory complications that are dealt with below.

### Investigations

The chest radiographic appearances are too variable for this investigation to be useful in establishing the likely microbial cause of the pneumonia. Thus the shadowing may be patchy and widespread or more confluent and confined to one or two lobes (Fig. 13.13). Involvement has been found to be unilateral in 65% and a lower lobe may be involved in three-quarters of cases [404]. Pleural effusions may occur in 7% or more of cases but are usually small [404,405]. Nodular shadowing may occur but is unusual [404]. Hilar gland enlargement is also an occasional but

**Fig. 13.13** Bilateral patches of micronodular shadowing in a patient with systemic illness but few respiratory symptoms other than cough. The clinical suspicion of *Mycoplasma pneumoniae* pneumonia was confirmed by serology.

inconsistent finding [210,404]. Radiographic shadowing usually resolves within 4–6 weeks, residual fibrosis being rare [406].

Gram stain of sputum may show some polymorphs and mononuclear cells but no predominant organism, mycoplasmas being too small to be seen by light microscopy, and sputum culture is frequently negative for pathogens as indeed is blood culture.

The white cell count is normal in about one-third of cases and the erythrocyte sedimentation rate and plasma viscosity usually raised, often markedly so. The coulter count may sometimes spuriously suggest a macrocytosis, this being the result of red cell agglutination. IgM cold agglutinins specific for the I antigen of red blood cells may be found at a titre of 1/32 or greater, or show a fourfold increase in about 50% of cases [407]. This test is usually done by combining the patient's serum with type O red cells in the laboratory. If clumping is noted, the serum is serially diluted and the test repeated, the titre reported being the highest dilution at which clumping occurs at 4°C. Cold agglutinins usually develop in the first week and a half of infection. This test tends to be more sensitive in iller patients, who have *M. pneumoniae* titres that exceed 1/128. A modified test may be carried out at the bedside by placing 1–2 mL of the patient's blood in a standard laboratory clotting (i.e. citrated) tube and placing it in iced water (or on the shelf of the ward refrigerator) for a few minutes [408]. Clumping of red cells is observed after about 3 min if cold agglutinins are present, the specimen reverting to its original appearance when rewarmed in the

doctor's pocket. The specificity of the cold agglutinin test for *Mycoplasma pneumoniae* is only in the order of 50% but a positive test is nevertheless suggestive of *Mycoplasma* infection when taken in the right clinical setting [409]. Cold agglutinins usually reach a peak 2–4 weeks after the onset of cough and fever and if they are not found early in the illness the test should be repeated after an interval [410].

About 30% of patients develop an antibody to *Streptococcus* MG that can form the basis of a serological test. As this test is less sensitive than the cold agglutinin test and as cold agglutinins are also detectable when it is positive, it is not usually carried out.

*M. pneumoniae* infection may occasionally be associated with antinuclear antibody production and the organism may also produce a phospholipid capable of giving false-positive serological tests for syphilis. However, neither of these characteristics are diagnostically useful.

There is at present no rapid, readily available means of making a diagnosis in cases of *Mycoplasma pneumoniae*, as the organism can only be cultured with difficulty in enriched artificial media containing antibiotics to suppress bacterial overgrowth. Even then culture takes 1–2 weeks before pinpoint colonies become visible [411] and very few clinical laboratories therefore offer this service. Diagnosis often relies on clinical suspicion in the acute stage of the illness and subsequent retrospective serological information to demonstrate a fourfold rise in specific antibody titres between the acute and convalescent blood samples. The CFT is still most commonly used, detecting

rising titres of antibody during the second week that peak at about the fourth [412]. A single titre of 1/128 or greater is also suggestive of infection within the previous few weeks or months. Such a test does not provide a sufficiently rapid answer to influence management and its chief usefulness is in epidemiological work. The sensitivity of the CFT may be as low as 54% [413]. This is improved by a more modern ELISA [414], which gives a specificity of 99% and sensitivity of 98% in patients with positive CFTs. The ELISA is designed to detect *Mycoplasma*-specific IgM and IgG, the IgM being most useful as its presence is more likely to indicate recent infection, the IgG being included as well because some patients display only an IgG response. Unfortunately this test too may not read positive until a week or so into the illness so that the result is unlikely to influence therapy.

The development of genetic probes for *Mycoplasma* nucleic acids has led to the commercial production of a rapid diagnostic test that detects *Mycoplasma* nucleotide sequences directly in clinical samples within 2 h by the attachment of radiolabelled DNA to *Mycoplasma* RNA (Gen-probe). A sensitivity of 95% and specificity of 85% was found on sputum from young adults with confirmed *Mycoplasma* pneumonia but the test was of limited value when applied to throat swabs [415]. Further tests that have been developed for rapid diagnosis include enzyme immunoassays for *Mycoplasma* antigen detection in sputum and nasopharyngeal aspirates, the reported sensitivity and specificity of which has ranged from good to indifferent [416,417]. PCR gives a reportedly high sensitivity and specificity and has the potential to give a rapid result but is a practicable proposition in very few centres [418].

### Treatment

Untreated *Mycoplasma* infection usually resolves gradually over the space of about 2 weeks and those cases of pharyngitis or tracheobronchitis are clinically indistinguishable from many viral upper respiratory tract infections. Most cases of pneumonia remain ambulatory and an antibiotic is started empirically; indeed in the present state of knowledge treatment is almost invariably started and often finished before diagnostic confirmation is available.

Cases of pneumonia in which *Mycoplasma* infection is suspected should be treated with an antibiotic that inhibits protein synthesis, erythromycin or tetracycline 250–500 mg 6-hourly in adults having been established as first-line therapy. Both these drugs have been shown to be effective in controlled trials in terms of diminishing the clinical manifestations of disease and in hastening radiographic clearing [419,420]. Tetracycline should be avoided in pregnant women as well as in children under the age of 9 years because of its effect on developing teeth. Doxycycline is similarly effective and may be adminis-

tered at a dose of 100 mg twice daily but the same constraints apply. The newer macrolides such as clarithromycin and azithromycin have been shown to be equally effective *in vitro*; indeed azithromycin has greater *in vitro* activity against *Mycoplasma* than either erythromycin or tetracycline [421,422]. Azithromycin and clarithromycin also appear to be as effective as erythromycin in a comparative clinical setting, with fewer adverse effects [423,424]. Another newer macrolide, roxithromycin, has also been shown to be clinically effective in treating *Mycoplasma* pneumonia [425]. Quinolones such as ciprofloxacin are also effective [426], whereas antibiotics that have their effect by disrupting cell walls such as the penicillins and cephalosporins are, not surprisingly, ineffective against *M. pneumoniae* which lacks a cell wall for them to attack. One disadvantage of the newer oral macrolides and quinolones is that they are presently 20–30 times more expensive than erythromycin and tetracycline.

Interestingly, the organism may remain culturable in sputum for several weeks after apparently effective antimicrobial therapy [391,392]. The reasons for this are unclear but it is possible to speculate that as well as attaching itself to the surface of cells *Mycoplasma* may also behave as an intracellular parasite or that the antimicrobials inhibit multiplication rather than killing the organisms. The ability of the organism to persist in the respiratory tract in this manner is presumably the cause of the observed tendency for the disease to relapse in a small but significant number of cases unless treatment is continued for 2–3 weeks. Thus, when *Mycoplasma* is strongly suspected or confirmed, treatment should, in the author's opinion, be continued for at least 2 weeks.

Anything but complete recovery in *M. pneumoniae* infection is exceptional, persistent respiratory symptoms occurring only rarely [394,427]. Clinical experience suggests that corticosteroids may be beneficial in cases of severe *Mycoplasma* pneumonia, but as such cases are rare there are no controlled trials to support this impression. It is not known whether treatment prevents the non-respiratory complications listed below. No effective vaccine against *Mycoplasma* infection has so far been developed.

### Complications

Although the majority of *M. pneumoniae* infections are sub-clinical or limited to the upper respiratory tract [428,429] and even those that cause pneumonia are generally benign [430], nevertheless occasional complications occur, sometimes with fatality [399,431,432].

All pulmonary complications are rare. They include massive pneumonic infiltration leading to respiratory failure [398], ARDS [399], large pleural effusions [433], lung abscess or cavities that usually resolve [434,435], unilateral hyperlucent lung (Swyer-James and MacLeod's

syndrome) [436] and diffuse interstitial fibrosis [437]. *Mycoplasma pneumoniae* may be complicated by secondary bacterial infection [438]. Chronic obliterative bronchiolitis (which may lead to organizing pneumonia) and bronchiectasis have also been described as complications [394,432,439–442].

The literature contains numerous case reports of extrapulmonary complications affecting every system of the body and usually occurring within 3 weeks of the onset of the illness. As *Mycoplasma* infection is common, some of these reports may be chance associations. Arthralgia, myalgia, diarrhoea and transient maculopapular erythematous rashes or urticaria are not uncommonly associated. Cold agglutinin-associated autoimmune haemolytic anaemia is well recognized; although usually mild, with a positive Coombs' test and increased reticulocyte count, it may occasionally be more severe, requiring blood transfusion and treatment with corticosteroids [428,443,444]. The production of cold agglutinins in *Mycoplasma* infection may be associated with Raynaud's phenomenon, presumably due to the agglutination of erythrocytes in the peripheral circulation when exposed to cold. An extreme form of this, with digital necrosis, may occur in patients with sickling haemoglobinopathies such as sickle cell anaemia. Other haematological associations that have been described include thrombocytopenia, thrombocytosis and DIC [383,399]. Other extrapulmonary complications range from the unusual to the extremely rare. The most serious are neurological and are said to occur in about 1 in 1000 cases [445]. These include meningoencephalitis, cerebellar ataxia, brainstem dysfunction, transverse myelitis, Guillain-Barré syndrome, cranial (including optic) neuritis and peripheral neuropathies; 10% of these patients may die and one-third may be left with some neurological deficit [397]. Direct invasion of nervous tissue by the organism has not been demonstrated (although it has been demonstrated in the CSF), leading to the supposition that there may be an immune basis for these and other extrapulmonary complications. Immune complex-related interstitial nephritis or glomerulonephritis may occur [446,447]. Cardiac complications include pericarditis and myocarditis with associated conduction defects, dysrhythmias and heart failure [448–450]. In addition to the rather common transient rashes referred to above, erythema multiforme, sometimes occurring as Stevens-Johnson syndrome (bullous eruption of the skin and mucous membranes with variable systemic manifestations), is described with *Mycoplasma* infection, as is erythema nodosum [428,440,451]. The cutaneous lesions usually clear within a week or two. Corticosteroids are sometimes used to settle the symptoms of Stevens-Johnson syndrome, although evidence of benefit is thin. Aside from transient diarrhoea, other possible gastrointestinal associations include anicteric hepatitis, acute pancreatitis and sialoadenitis [428]. Apart from myalgia

and arthralgia (which may be protracted), migrating polyarthritis affecting large joints may unusually occur and the organism has occasionally been isolated from synovial fluid [452]. Direct extension of infection from the pharynx to the tympanic membrane via the eustachian tube may cause bullous myringitis.

### ***Chlamydia pneumoniae***

*Chlamydia* is a genus of small obligate intracellular coccoid Gram-negative bacteria containing three species, *C. pneumoniae*, *C. psittaci* and *C. trachomatis*. The following sections are mainly concerned with infection caused by the first two organisms. *C. trachomatis* is almost exclusively a parasite of humans and although it may unusually cause respiratory illness, in adult practice it is more familiar as a major cause of blindness in endemic areas and of genitourinary disease. About 300 cases of respiratory chlamydial disease are reported to the Communicable Diseases Surveillance Centre every year, most cases occurring in patients aged 15–44 years [453]. It is thought that about three-quarters of these infections are due to *C. psittaci* [453].

#### ***C. psittaci pneumoniae (psittacosis)***

*C. psittaci*, being filterable, was once thought to be a virus but is now recognized as a special type of intracellular bacterium that possesses a cell wall and both DNA and RNA. It divides by binary fission and is susceptible to certain antibiotics [454]. *C. psittaci* infection is distributed widely among various members of the animal kingdom [455], particularly avian species, an outbreak of respiratory infection in humans having been linked with imported parrots in the 1890s, hence the term 'psittacosis' from the Greek word *psittakos* meaning parrot [454–456]. The more general term 'ornithosis' is sometimes used following the recognition that the same disease can be contracted from other birds including budgerigars and other parakeets, cockateels, pigeons, doves, ducks and turkeys. Although both words are entrenched in common useage, it can be seen that other modes of transmission may occur and *C. psittaci pneumoniae* is therefore a more accurate term.

#### **Epidemiology**

*C. psittaci* may be hosted by many avian species, both wild and caged, including domestic poultry such as ducks and turkeys. All are susceptible and disease is occasionally transmitted to humans [456]. However, a history of contact with birds in human *C. psittaci* infection is recorded in less than one-third of cases [457], and when it does occur it need not be prolonged. This observation raises the possibility of other methods of transmission, such as animal to human or human to human [455].

Psittacine infection is an occupational hazard of veteri-

narians, pet-shop workers, taxidermists, zoo staff and poultry workers, apart from those who handle only dressed fowl [458,459]. Bird fanciers are therefore not only at risk of extrinsic allergic alveolitis (see Chapter 31) but also of *C. psittaci* pneumonia, and in the UK budgerigars are thought to account for half of all sporadic cases in which a source is identified [460]. A similar proportion of the much smaller total number of cases reported in the USA is related to the ownership of pet birds. When a caged bird is responsible for transmitting infection it may appear ill, although this is not always the case as asymptomatic carriage can occur. *C. psittaci* can be recovered from the tissues, feathers and excreta of infected birds and the organism is generally assumed to reach the human respiratory tract as a result of the inhalation of small particles of dried excreta or other organic material. Some of those human cases in whom no avian source is evident may arise from other animals, such as sheep, newborn lambs, cattle and cats [461–466]. Person-to-person spread, though formerly regarded as rare, may be more common than is thought and presumably occurs by droplet aerosol. Two putative episodes have been recorded in the literature in which the index case has passed infection to 11 and 25 contacts respectively, with fatal results in 13 of them [467,468]. A mild outbreak of *C. psittaci* infection has also been reported in an English boys' boarding school, where 24 cases occurred with no obvious point source [469]. It is possible that such cases may have been caused by serological cross-reactivity with *C. pneumoniae*, which was at the time unknown. The vast majority of cases reported are sporadic rather than epidemic, with no apparent pattern of seasonal variation [470,471]. Food-borne transmission occurring as a result of the ingestion of infected poultry has not been described.

### Incidence

The true incidence of *C. psittaci* pneumonia in the community is unknown, as published figures reflect the diligence with which the diagnosis is pursued. The number of cases reported annually in the UK (through the Public Health Laboratory Service) has exceeded 300 [470] and two English hospital series of community-acquired pneumonia have found that *C. psittaci* accounts for 1.5% and 5.5% of cases [165,167]. The figure obtained by a British Thoracic Society multicentre study was 3% [35]. A survey carried out in a population of about 30 000 based around Cambridge, England detected 18 cases between 1975 and 1983, giving an annual incidence of 1 in 2000. The rate in one rural practice of under 5000 patients within this same area was as high as 1 in 200 [471]. An avian source of infection was detected in only 17% of cases. It seems probable that all these foregoing reporting rates are overestimates of *C. psittaci* infection as the studies were carried out before *C. pneumoniae* was recognized, the CFTs that were

used having been genus specific but not species specific. Only 40–60 cases are reported annually in the USA despite the much larger population in that country. It has been suggested that this discrepancy may be explained by measures such as the medication of imported cage birds and the treatment of poultry feed with tetracycline [472].

### Pathology

*C. psittaci* most commonly has a two-stage developmental cycle, the organism entering the respiratory tract and being transported via the blood to the reticuloendothelial cells of the liver and spleen, where replication takes place intracellularly. Large numbers of organisms then cause a secondary bacteraemia, invading the lungs and other organs haematogenously. It is now thought that in some cases immediate infection of the respiratory epithelial cells may progress directly to pneumonia without the bacteraemic phase, these patients having a short incubation period of up to 3 days [473]. Those cases coming to post-mortem examination show areas of consolidation that are more common in the lower lobes. The bronchiolar and bronchial epithelium shows desquamative and necrotic changes and the alveoli and bronchioles contain a fibrinous exudate. A variable degree of lymphocytic infiltration is found in the interstitium. Small areas of haemorrhage are present and macrophages contain inclusion bodies. The liver and spleen may be enlarged and may contain areas of focal necrosis. The hilar lymph nodes may be enlarged [474].

### Clinical features

Symptomatic *C. psittaci* infection typically occurs in adults of working age and is unusual in children [470,475]. The incubation period is usually 1–2 weeks but may vary from a few days to as long as 4 weeks (see above). In some individuals infection is subclinical [471], while in others symptoms may range from a mild 'flu-like' illness to chlamydial bronchitis or pneumonia, which in the severest cases may be fulminant with multiple organ involvement.

The onset of illness may be abrupt with rigors or there may be a gradual onset of malaise, chills and fever. Systemic symptoms are usual and may include myalgia, arthralgia and headache, which may be severe. A sore throat is sometimes present. Cough may occur from the onset or after a few days, and may be either dry or productive of mucoid sputum sometimes flecked with blood. Pleuritic pain may occur. Some patients experience nausea, vomiting and abdominal pain. Epistaxis may occur. Hepatitis, endocarditis, acute renal failure (in an unspiciated case), Stevens–Johnson syndrome, erythema nodosum and other vasculitic rashes have been described [475–479].

Physical examination of the chest may reveal crackles

over infected areas of lung but most patients do not have impressive signs of consolidation [472,475,480]. Palpable splenomegaly may be present.

### Investigation

The white count is frequently normal. An eosinophilia is sometimes seen during recovery. Non-specific findings may include mild anaemia and proteinuria. Liver function tests are commonly abnormal, sometimes showing mild cholestasis. As with other acute pneumonias, the chest radiographic appearances are highly variable and non-discriminatory [210,475]. The infiltrate is most commonly described as 'patchy', but is not infrequently confluent to the extent of being lobar. Shadowing is bilateral in about 12% of cases. Pleural effusions may occur but are usually small. Radiographic changes in *Chlamydia* pneumonia are relatively slow to clear, complete resolution having been recorded in about 50% of cases by 7 weeks [210,475]; 28% of serologically positive and symptomatic patients have been found to have normal chest radiographs, implying the presence of chlamydial bronchitis rather than pneumonia [475]. Many of these cases are likely to have been caused by unrecognized *C. pneumoniae* infection.

Routine blood cultures are negative. If sputum is obtained, it is often found to contain no pathogens on routine Gram stain and culture and a firm diagnosis relies upon serological confirmation. The most widely used test is the CFT. Unfortunately this uses chlamydial lipopolysaccharide antigen, which is genus specific but which does not distinguish between the three different *Chlamydia* species, so that many patients diagnosed in the past as having psittacosis on the basis of a positive CFT in fact had *C. pneumoniae* infection [481]. Both acute and convalescent serum samples should be taken. Complement-fixing antibodies start to rise by the end of the second week of illness and a fourfold rise in titre is confirmatory. Some have accepted a single high titre (1/256) as confirmatory; although others would regard a single titre of greater than 1/32 as sufficient grounds for a presumptive diagnosis when taken in conjunction with a compatible illness, false positives do occur and the significance of single raised titres may be problematical. It should be noted that early treatment with an appropriate antibiotic may delay the rise in antibody titre, which is only detected some weeks later at follow-up.

Species-specific microimmunofluorescence (MIF) is available in some laboratories and detects *C. psittaci* IgM and IgG. IgM is used to detect current or recent infection, a titre of greater than 1/8 being taken as indicative and falling in the convalescent sample. However, problems may arise because the organism is antigenically diverse with at least 11 serotypes (or 'serovars'), not all of which may be included in the test. One practical method of arriving at a serological diagnosis is to use CFT to detect the

genus and MIF to detect *C. pneumoniae* (see below), or *C. psittaci*, depending upon the availability of the test, so that the other species can be identified by a process of exclusion.

Techniques for chlamydial antigen detection using an ELISA or direct immunofluorescence have been developed but are not yet readily applicable for respiratory diagnostic purposes [482,483]. PCR has been used to detect *Chlamydia* species antigen but is not generally available.

*C. psittaci* can be grown on cell monolayers; however, its culture presents a considerable potential hazard to laboratory personnel in whom deaths have occurred as a result of infection [456,484]. Attempts to culture it are therefore carried out infrequently and then only with stringent precautions and in laboratories with special expertise [485].

PCR techniques have been used in research settings to detect *C. psittaci* and *C. pneumoniae* in sputum but are not generally available [486].

False-positive serological tests for syphilis may occur as with *Mycoplasma pneumoniae*.

### Treatment

Tetracycline or doxycycline are equally effective, the dose of tetracycline being 500 mg 6-hourly and that of doxycycline 100 mg twice daily. Gradual improvement after 2–3 days is the rule but relapses may occur [487] so that it is sensible practice to treat for 3 weeks. Cases in childhood are rare but when they do occur they may be treated with erythromycin, which is probably as effective as tetracycline, although there are no controlled trials. Penicillin is relatively ineffective. Rifampicin has been successfully used in the treatment of *C. psittaci* endocarditis [488]. Supportive measures are applied as necessary.

### Prognosis

The mortality from *Chlamydia* pneumonia before the availability of antibiotics was in the order of 20–40%. Milder cases of *C. psittaci* infection often settle spontaneously at 1–2 weeks or might enter a more chronic phase lasting for some months. Mortality following appropriate treatment is low, at around 1%.

### Complications

As with any acute pneumonia, occasional fulminant cases may occur that can result in death due to hypoxia or overwhelming sepsis [489]. Neurological involvement with meningoencephalitis may result in lethargy, confusion or delirium progressing to stupor and coma [490]. Other complications have included myocarditis, pericarditis and endocarditis, which should be considered in cases of valvular disease where, despite the suspicion of this diag-

nosis, blood cultures are repeatedly negative [488,490–493]. The author has seen inappropriate secretion of ADH in a severe case of *C. psittaci* pneumonia.

### *C. pneumoniae* pneumonia

*C. pneumoniae* is not a new organism but a relatively newly recognized one. The first isolate was obtained from a conjunctival culture of a Taiwanese child (hence the laboratory designation TW-183) in 1965. It was subsequently recognized as a respiratory pathogen by Marrie *et al.* [494] who isolated it from adults with acute respiratory symptoms in 1986 and at first referred to it as *C. psittaci* strain TWAR (from TaiWan Acute Respiratory). It was subsequently declared the third *Chlamydia* species and renamed *C. pneumoniae*. Apart from TWAR, one further serological variant, IOL-207, has been described. Studies on banked serum have shown that infections by this organism were as common 35 years ago as they are today.

### Epidemiology

Infection by *C. pneumoniae* is very common worldwide, about 50% of the population having serologically detectable antibodies to this organism by early adult life. As with other potential pathogens, carriage of the organism in the throat may be unaccompanied by symptoms so that its relevance as a cause of infection has sometimes been questioned. Humans are the only known reservoir of infection, which is probably spread from person to person by aerosolized droplets, although direct evidence is lacking. A subject may be culture positive in the absence of serological evidence of infection, and it is possible that asymptomatic carriers may play a role in the spread of infection although this is also speculative. Infection is endemic and common from school age onwards. Reinfection is also thought to be common and epidemics have been described in closed communities [495]. It is likely that some of these may have been attributed to psittacosis in the past.

### Incidence

It is now thought that *C. pneumoniae* infection causes 6–9% of cases of community-acquired pneumonia admitted to hospital [494,496,497]. These form only a small minority of all cases of infection, 70–90% of which are estimated to be subclinical [498]. A population survey carried out in the Seattle area by Grayston [499] found the incidence of *C. pneumoniae* pneumonia to be 1 per 1000 per year compared with a rate for *M. pneumoniae* of 1.8 per 1000 per year. The highest incidence of pneumonia caused by the former organism was in the elderly, whereas by contrast the latter organism was a more frequent cause of pneumonia in chil-

dren. Infection commonly causes acute bronchitis rather than pneumonia.

### Clinical features

There are no reliable clinical features to distinguish infection caused by *C. pneumoniae* from that caused by *M. pneumoniae* or indeed from other pyogenic bacterial pneumonias. The illness is generally mild and self-limiting. Prolonged subacute bronchitis, lasting days or weeks, or a mild pneumonic illness is often preceded by a sore throat and the patient does not usually require admission to hospital [500,501]. However, more serious illness may occur and fatalities have been reported, especially in the presence of serious coexisting disease [494,502]. It has not always been clear in such cases whether *C. pneumoniae* has been the main cause of the illness or a co-pathogen such as *Strep. pneumoniae* or *H. influenzae* [503]. Episodes of reinfection may occur and tend to cause milder illness. Sinusitis, otitis media, tonsillitis and laryngitis may also result from *C. pneumoniae* infection. Exacerbations of asthma have been described following *C. pneumoniae* infection and it has been suggested that this might be causal in some cases, although this is doubtful [504]. Serological evidence of recent *C. pneumoniae* infection in exacerbations of chronic obstructive pulmonary disease has been described but is unusual [505].

### Investigations

The white cell count is often normal and the erythrocyte sedimentation rate raised. The chest radiograph commonly shows a segmental infiltrate, although more extensive bilateral radiological change may be seen in patients with severe illness and pleural effusions may uncommonly occur [506,507].

There are several laboratory tests for diagnosing *Chlamydia* infection. The comments on the CFT made for *C. psittaci* infection also apply to *C. pneumoniae*. Other tests that can distinguish between species are often only carried out in specialist laboratories. One such species-specific test is MIF, which can also use *C. pneumoniae*-specific antibodies [508]. This test separately measures IgM and IgG antibodies, the IgM antibodies developing within a few weeks of primary infection and falling off on recovery, and the IgG antibody developing by 2 months and remaining detectable for years, so that it may be used to estimate the prevalence of infection in a population. In repeat infections IgM does not develop and IgG develops faster and to a higher level. The usual criteria for acute infection by *C. pneumoniae* on paired samples are a fourfold or greater rise in IgG antibody, and on a single sample an IgM antibody titre equal to or greater than 1/16 and/or IgG equal to or greater than 1/512 [509]. However, treatment with an appropriate antibiotic may suppress antibody responses

and the presence of rheumatoid factor may cause a false-positive result. MIF remains the most sensitive method for diagnosing *C. pneumoniae* infections. Chlamydial antigen detection methods include an ELISA and a direct immunofluorescent test as mentioned under *C. psittaci*.

*C. pneumoniae* may be cultured from throat swabs on to an established cell line such as HEp-2 over the space of about 3 days, these specialized techniques being available to laboratories with cell culture capability.

PCR has been developed to detect minute amounts of *C. pneumoniae* DNA. This is still largely a research tool but has been shown to have a high degree of sensitivity and specificity.

### Treatment

Early recommendations for the treatment of *C. pneumoniae* was with a 2-week course of tetracycline or doxycycline, clinical relapses being thought to be somewhat more common with erythromycin if this was given for less than 3 weeks [498]. However, the newer macrolides such as clarithromycin and azithromycin have also been shown to be effective, clarithromycin being particularly active *in vitro*, although controlled clinical trials are lacking [510,511]. Fluoroquinolones are also effective.

### Complications

A number of extrapulmonary complications of *C. pneumoniae* have been described. These include Guillain-Barré syndrome [512], encephalitis [502,513], erythema nodosum, thyroiditis [509], reactive arthritis [514], myocarditis [515] and possible endocarditis [516]. It has been proposed, mainly on the basis of serological evidence in case-control studies, that *C. pneumoniae* infection is associated with coronary artery disease. However, it cannot be assumed that this association is causal, as some authors found that tobacco smoking was an independent risk factor for *C. pneumoniae* infection, which tended to negate the statistical significance of the association [517,518]. Others have disputed this, pointing out that the organism has been recovered from atheromatous plaques and suggesting that it may be responsible for low-grade inflammation and increased plasma fibrinogen concentrations [519].

### Other chlamydial infection

It is unusual for the other species, *C. trachomatis*, to cause pneumonia in adults, although isolated cases have occurred in immunocompromised patients [520]. However, non-lymphogranuloma venereum strains of this organism may produce pneumonia in infants, infection presumably being communicated to the child from the mother's genital tract [521,522]. These strains belong to

the serotypes D-K and are also responsible for non-gonococcal urethritis, cervicitis, endometritis and inclusion conjunctivitis [523]. Lymphogranuloma venereum strains ordinarily produce inguinal buboes but have on rare occasions been described as causes of pneumonia, pleural effusion and mediastinal lymphadenitis, five cases of which have occurred in laboratory researchers exposed to the organism [523]. Treatment is with tetracycline (in adults) or a macrolide [523,524]. The general prevalence and significance of a 'new' organism known as *Chlamydia*-like microorganism Z, which has been described as a possible aetiological agent in 2.6% of 308 patients with community-acquired pneumonia in Israel, remains uncertain. These patients appeared to respond to erythromycin [525].

### *Coxiella pneumoniae* (Q fever)

Q fever is an infectious zoonosis that is an unusual cause of pneumonia but one that needs to be considered in the differential diagnosis when another infective agent is not readily identifiable. It is caused by a rickettsial organism that has been assigned its own genus because it differs from other rickettsiae in several respects, including both its ability to survive outside the host and its transmissibility to humans by inhalation rather than the bite of an insect vector. It was originally known as *Rickettsia burnetii* after Burnet, who identified the organism from the blood of patients with Q fever [526], a febrile illness noted to afflict abattoir workers in Queensland, Australia [527]. 'Q' stands for 'query', as the term Q fever was originally used at a time when the cause was unknown and its usage continues today. The present name of the organism is *Coxiella burnetii* after Cox who independently found it in ticks in Montana, USA. *C. burnetii* is a small bacterium that is an obligate intracellular parasite. It divides by binary fission and is fastidious in its growth requirements, so that diagnosis is usually by serological testing.

### Epidemiology

*C. burnetii* is distributed worldwide in mammals, both domestic and wild. The main reservoir of infection in the UK and North America is cattle and sheep [528]. Humans are an incidental host of no particular value to the organism, which is mainly transmitted to humans by inhalation, probably in the form of spores that can withstand desiccation [529,530]. Infection in cattle and sheep is subclinical, so there is no commercial reason for farmers to eradicate it. Infected animals may excrete large numbers of *C. burnetii* in milk, urine, faeces and in the products of parturition. Humans are highly susceptible to infection if they inhale dried particles from any of these sources. Ingestion of milk is another potential source, although infection does not occur if pasteurization has been carried out [531]. Q fever

is an occupational hazard of farmers, slaughter-house workers, veterinarians, hide handlers, butchers and indeed all who come into contact with cattle, sheep and goats, including personnel at medical research institutions [532,533]. It may also occur in laboratory workers [534]. The illness may occur both sporadically and in sudden outbreaks and it is important to realize that it may occur in patients from whom no history of animal contact can be obtained. An outbreak has been reported in town-dwellers in Wales in whom infection was supposed to have been disseminated by straw and other debris falling from farm vehicles as they passed through the locality [535]. The largest UK outbreak occurred in the urban West Midlands, possibly as a result of the wind-borne spread of infection from adjacent farmland [536]. Person-to-person transmission of Q fever has been described but is probably exceedingly rare [537].

### ***Incidence***

Q fever is almost certainly underdiagnosed as a result of the mild nature of the infection in the majority of cases, which are probably often attributed to influenza [538,539]. Thus of 111 cases diagnosed in a Melbourne abattoir only eight had pneumonia [532]. About 50–100 cases are confirmed serologically each year in the UK [540]. *Coxiella* pneumonia probably accounts for approximately 1% of cases of community-acquired pneumonia admitted to hospital in the UK [167,281]. It appears to be more common in spring and early summer in England and Wales, possibly reflecting lambing and the movement of livestock to market [540].

### ***Pathology***

Few cases have come to postmortem examination and those that have show non-specific pneumonic changes [541]. The inflammatory response is mainly mononuclear [474,542]. A detailed microscopic description has been made of a *C. burnetii* inflammatory pseudotumour that was resected on the radiological suspicion of carcinoma of the lung [542].

### ***Clinical features***

The manifestations of Q fever can be very varied but typically the illness is characterized by the sudden onset of high fever with rigors, headache (often severe) and myalgia after an incubation period of 2–5 weeks [532]. Nausea, vomiting and diarrhoea occur less commonly. There may be no cough or other respiratory symptoms, pneumonia occurring in less than 8% of an Australian series containing over 100 cases [532]. Admission to hospital with pneumonia was required in 8 of 29 cases of Q fever detected in an outbreak in South Wales [535]. A recent

Spanish study of 164 cases showed that about half had no respiratory symptoms. Cough was common in those that did have respiratory symptoms and about one-third of patients had pleuritic pain [543]. Most cases with lung involvement have single or multiple pulmonary infiltrates on the chest radiograph and a minority has a more rapidly progressive pneumonia. The physical signs are similar to those described for viral pneumonias (see below) but in addition hepatosplenomegaly occasionally occurs [532,544].

### ***Investigations***

The white blood cell count is often normal. Thrombocytopenia has been described in about 25% of cases and a reactive thrombocytosis may occur during the recovery phase [545]. Hepatic transaminases are commonly slightly raised and it is worth considering the diagnosis when this finding occurs in the absence of positive hepatitis serology. The diagnosis is confirmed retrospectively in most laboratories and relies on a clinical index of suspicion high enough to lead to appropriate serological testing (usually CFT). *C. burnetii* undergoes an antigenic change that produces two antigenic polysaccharides at different stages of infection. Paradoxically, phase II antibody can be detected first; phase I antibody remains at a low titre unless the disease enters a chronic stage (see below), in which case it exceeds the titre of phase II antibody. Antibodies may take 1–2 weeks to become detectable, a fourfold rise in titre of phase II antibody between acute and convalescent samples being diagnostic of acute infection. Titres fall gradually thereafter but may persist for years [546]. Apart from CFT, more recent serological developments include indirect immunofluorescent antibody tests, an ELISA and microagglutination tests [547]. PCR has also been used.

The chest radiograph is not discriminatory. Patients with Q fever pneumonia tend to show predominantly homogeneous unilateral or bilateral lower lobe shadowing of segmental or subsegmental distribution but the appearances are variable [548,549]. Pleural effusions may occur [550].

*C. burnetii* can be cultured from blood and other specimens but the technique requires guinea-pig inoculation and is hazardous to technical staff, necessitating special laboratory techniques and precautions, so that it is rarely carried out.

The Weil–Felix reaction, which is positive in other rickettsial infections, gives a negative reaction in Q fever.

### ***Treatment***

Q fever, whether associated with pneumonia or not, may be self-limiting and it is not entirely clear that therapy with antibiotics shortens its course, although the impression is that it does [532,551]. Q fever pneumonia may be fatal in

rare instances or may be associated with serious complications [541]. As the organism is sensitive to tetracycline *in vitro*, it is logical to treat with this antibiotic at a dose of 500 mg 6-hourly for about 3 weeks. Doxycycline 100 mg 12-hourly may also be used and may be more effective than erythromycin 500 mg 6-hourly, which is another alternative [551,552]. Rifampicin has been added in sicker patients with apparent good effect [547]. Untreated, the fever usually settles in 2–14 days but convalescence may be protracted [532,553]. Isolation is not ordinarily required as person-to-person spread of infection is rare, although immunocompromised patients may be more susceptible. A vaccine has been developed for those at risk such as abattoir workers but is not generally available [554].

### Complications

These are unusual and when they do occur are the result of the infection entering a chronic phase. The most serious manifestation is endocarditis, which usually affects a diseased native aortic or prosthetic valve [555,556]; 11% of 839 cases of confirmed Q fever reported between 1975 and 1981 developed this complication of culture-negative endocarditis, which is sometimes associated with a vasculitic rash. There are no controlled trials but successful treatment may require the use of combinations of antibiotics for months or years and valve replacement may be required [547,557]. Endocarditis may occur several years after the acute infection and the diagnosis is confirmed by a phase II antibody titre exceeding that of the phase I titre in the presence of negative blood cultures. It is not clear whether adequate treatment of acute Q fever infection prevents this sequel, which probably occurs as the result of latent hepatic infection.

Other complications include intravascular graft infections, meningoencephalitis, myocarditis, pericarditis, hepatitis with granulomas on liver biopsy, uveitis, osteomyelitis, haemolytic anaemia and epididymo-orchitis [540,557–559].

### Staphylococcal pneumonia

*Staph. aureus* is one of the less common causes of pneumonia acquired in the community but is nevertheless of great interest to clinicians because it may cause sudden and devastating illness. The same organism is an important cause of hospital-acquired infection and should be one of the foremost considerations when treatment of any severe case of pneumonia is planned. Treatment of infection with this organism has become more difficult because of the emergence of multidrug-resistant strains.

Staphylococci are members of the family Micrococcaceae and the specific name '*aureus*' has been given because most colonies of *Staph. aureus* appear golden-yellow when growing on agar. *Staph. aureus* grows well

both aerobically and anaerobically and is the only member of the genus that produces coagulase, a plasma-clotting enzyme, hence the term 'coagulase-positive staphylococcus'. It is a highly adaptable, non-spore-forming, non-motile pathogen, able to colonize rapidly and to penetrate damaged skin or mucosal surfaces. It has a specialized cell wall and can elaborate numerous toxins that contribute to its pathogenicity [560]. Most strains are surrounded by an antiphagocytic polysaccharide capsule or slime layer that affords it protection from polymorph attack, thereby increasing its virulence [561]. These encapsulated forms are better able to gain access to the bloodstream and to produce bacteraemia, unencapsulated forms being more likely to be contained locally in tissues. Paradoxically, if unencapsulated forms do gain access to the blood, e.g. via a contaminated intravenous line or from a drug addict's needle, they are more likely to produce the symptoms of septic shock or DIC, in the same way that DIC occurs with Gram-negative sepsis [562,563]. *Staph. aureus* has proved itself to be a frighteningly adaptive organism over the years, well able to develop resistance to antibiotics as the emergence of first penicillin-resistant *Staph. aureus* and now MRSA has shown only too well.

### Epidemiology

The main reservoir for *Staph. aureus* is humans, 30–50% of healthy adults being colonized, 10–20% persistently so [564]. Large numbers of these organisms may be carried asymptomatically, particularly in the anterior part of the nose. It is unknown why some should be carriers and others not, but higher carriage rates have been noted in type 1 diabetics, intravenous drug users, those on haemodialysis, surgical patients and those with AIDS [564–566]. *Staph. aureus* is an extremely hardy organism that can survive for some months outside its host and can be transferred from person to person both in particles suspended in air and by direct contact with skin or inanimate objects. Most hospital transmission is probably from the hands of healthcare workers who are transiently colonized by contact with infected patients or from their own reservoirs. Given these circumstances, it is unsurprising that outbreaks of *Staph. aureus* infection sometimes sweep through hospital wards [567].

In order that *Staph. aureus* may cause pneumonia it has to reach the lungs either via the trachea or by haematogenous spread in all cases other than those in which direct spread results from chest trauma or surgery. Nosocomial *Staph. aureus* pneumonia is favoured by tracheal intubation [568] and by conditions producing an impaired cough reflex, so that it has been found to be a common microbial isolate in cases of hospital-acquired pneumonia, coming second only to *Ps. aeruginosa*, and being particularly associated with diseases that impair conscious level [142,569]. Cases of staphylococcal pneumonia in the community may occur

in previously healthy people and are usually the sequel to a viral upper respiratory tract infection, therefore tending to be most common in the first few months of the year; indeed an association with influenza is well recognized so that the admission of a few cases of staphylococcal pneumonia to hospital may herald the onset of an influenza epidemic [570]. This was true in the large 1957 epidemic in which staphylococcal pneumonia was a significant cause of death and it continues to be so, a review of 61 community-acquired cases showing an association with influenza in about half [571]. At times when influenza is not epidemic, community-acquired staphylococcal pneumonia is uncommon in adult practice. *Staph. aureus*, in company with *Ps. aeruginosa*, is one of the major pathogens of the lower respiratory tract in cystic fibrosis (see Chapter 30).

*Staph. aureus* pneumonia may also result from bacteraemia. This may arise following direct invasion through breaks in the skin or at sites of pyogenic soft tissue infection, particularly where levels of hygiene are low as may be the case in developing countries or in communities where parenteral narcotic abuse is prevalent. The organisms may also gain access through prolonged intravenous cannulation or instrumentation sites or as a result of haemodialysis; having gained entry, they may be disseminated to various organs and structures including the lungs [572–574]. In all these cases, septic and thrombotic material may reach the lungs directly from a peripheral vein or sometimes from endocarditis involving the tricuspid valve (see Fig. 15.1) [19]. Although the source may be obvious, such as an infected wound, a burn, an eczematous skin lesion or marks of self-injection, at other times it may be inapparent, in which case the bacteraemia may be termed 'primary'.

The defence mechanisms in staphylococcal infection include not only complement-associated polymorphonuclear attack but also the phagocytic capacity of pulmonary alveolar macrophages, so that patients whose immune systems are compromised are more susceptible to *Staph. aureus* infection as they are to other pathogenic organisms [575]. One study of patients infected with HIV who were being investigated for lower respiratory tract infection found evidence of *Staph. aureus* pneumonia in 6%, AIDS having been diagnosed in most of these patients [576]. *Staph. aureus* pneumonia has been found to be more likely in HIV-infected patients who are drug abusers or who give a previous history of *Pneumocystis carinii* pneumonia [577]. Patients recovering in hospital following solid organ transplant are also more liable to *Staph. aureus* and other bacterial infections [578].

### Incidence

*Staph. aureus* has been estimated to be responsible for 1–2.4% of cases of community-acquired pneumonia requiring hospital admission [35,167]. *Staph. aureus* is

second only to *E. coli* in terms of causation of hospital-acquired infection as a whole and it more or less shares the honours with this pathogen as the commonest cause of hospital-acquired bacteraemia [566,579]. *Staph. aureus* may be a responsible pathogen in 10–16% of cases of nosocomial pneumonia [34,569].

### Pathology

In cases where infection has been fulminating, the lungs are heavy and waterlogged with oedema fluid that may be haemorrhagic and the bronchial mucosa is very inflamed. In those where the illness has been more protracted, there are features to suggest that the infection progresses from an acute necrotic bronchitis or bronchiolitis to produce focal areas of consolidation. These may break down to form ill-defined abscess cavities and, if extensive, may result in honeycombing of the lungs [474].

### Clinical features

Community-acquired staphylococcal pneumonia in its severest form usually occurs within a few days of influenzal symptoms and, if appropriate treatment is withheld, results in a prostrating illness with rising fever, cough, breathlessness and bacteraemic shock that can result in death within a few hours. Less severe cases may differ little in their presentation from pneumococcal pneumonia, except that abscess formation is more common and may be the dominant feature. *Staph. aureus* pneumonia should be suspected in any severe pneumonia and in less severe cases if response to antipneumococcal antibiotics is unsatisfactory or if cavitation or other evidence of progressive sepsis becomes apparent. The complications of staphylococcal pneumonia are discussed below. Unsurprisingly, adult hospital-acquired *Staph. aureus* pneumonia tends to occur in an older population with pre-existing illness that is commonly pulmonary and this complication is often first diagnosed in intubated patients on intensive care units [580]. Occasionally the painless desquamating rash otherwise associated with toxic shock syndrome may be found [581,582].

### Investigations

The chest radiograph may show a wide spectrum of change. Infiltrates may be localized to a single lobe and the shadowing may be confluent. Multiple more patchy shadows may also occur and these are sometimes rounded. These appearances may be associated with cavitation, which may also be multiple and bilateral. The development of cavities always raises the possibility of staphylococcal pneumonia (Fig. 13.14). Sometimes thin-walled, air-containing cavities known as pneumatoceles appear [583]. These are more common in young adults and

**Fig. 13.14** Cavitating staphylococcal pneumonia in the right upper lobe of a previously healthy 41-year-old man who developed fever and cough productive of mucopurulent sputum following influenza.

children. They sometimes reach enormous size, causing respiratory embarrassment in their own right. It is likely that they arise from small cavitating abscesses, the surrounding consolidation allowing air to enter the space on inspiration but preventing its escape on expiration [584]. When treatment of pneumonia is successful, these pneumatoceles may disappear with surprising rapidity. Complicating effusions and pneumothoraces may be seen but

the absence of so-called typical changes does not exclude the diagnosis [585].

There is usually a neutrophil leucocytosis but sometimes low white cell counts are found and anaemia often develops when bacteraemia is present. A low platelet count may indicate the development of DIC, in which case the prothrombin time and clotting time are prolonged.

Microscopic examination of the sputum may show grape-like (*staphyle* is ancient Greek for 'bunch of grapes') clusters of Gram-positive cocci mixed with neutrophils and inflammatory debris, these appearances being highly suggestive of staphylococcal pneumonia. However, interpretation may be difficult as the cocci can be relatively isolated, sometimes occurring singly, in pairs or in chains.

The organism is frequently isolated from both sputum and blood cultures and standard methods exist to enable microbiology laboratories to differentiate between staphylococci that are coagulase positive (i.e. *Staph. aureus*) and those that are coagulase negative (e.g. *Staph. epidermidis*) on the first day of isolation [586–588]. Although false-positive sputum cultures may occur as a result of nasopharyngeal colonization, false negatives are unusual in the presence of pneumonia [589]. *Staph. aureus* can often be isolated from blood in bacteraemic cases despite the prior commencement of an appropriate antibiotic, particularly if there is a septic focus. High spikes of fever, such as may occur during rigors, are particularly good times to draw blood for culture, this being positive in one-quarter to one-third of cases of *Staph. aureus* pneumonia [589]. The organism may also be grown from associated pleural effusions.

#### **Treatment of methicillin-sensitive *Staph. aureus* pneumonia**

Most strains of *Staph. aureus* produce  $\beta$ -lactamases so that it has long been the exception for these organisms to be sensitive to penicillins, such as benzylpenicillin, phenoxymethylpenicillin and the aminopenicillins (ampicillin, amoxicillin), even if the infection is acquired in the community. This is the case on both sides of the Atlantic, a figure of only about 5% being commonly quoted for penicillin sensitivity [564]. Over a decade ago Lacey [590] noted that 80% of hospital- and community-acquired *Staph. aureus* were penicillin resistant in the health district in which he worked. Intravenous benzylpenicillin may be used in those relatively few cases that are sensitive at a dose of 2.4 g (4 megaunits) 4–6 hourly but for the most part it is normal practice when *Staph. aureus* is suspected as a cause of pneumonia to treat with a  $\beta$ -lactamase-resistant antibiotic, of which flucloxacillin is preferred as drug of first choice in UK at a dose of 1–2 g i.v. 4–6 hourly for 48 h, thereafter continuing either parenterally or orally according to response. Treatment for 2 weeks is usually sufficient in uncomplicated cases but a minimum of 4 weeks of treatment is usually needed if an intravascular source of infec-

tion, such as right-sided endocarditis, is suspected (initial gentamicin being added in this circumstance). Flucloxacillin is unavailable in the USA, where options include intravenous oxacillin or nafcillin followed by dicloxacillin orally. Treatment for 2 weeks usually suffices, although this may need to be prolonged in severe or complicated infections, in which case other antistaphylococcal antibiotics may also need to be added. Options include rifampicin, which is a very potent antistaphylococcal drug that can be prescribed either orally or parenterally at a dose of 600 mg 12-hourly [591]. It must not be used alone or resistance will develop and its use in conjunction with other antistaphylococcal antibiotics is required [592].

For the patient with a history of delayed-type non-severe penicillin allergy a first-generation cephalosporin (e.g. intravenous cefradine or cefazolin) may be used; in cases of severe infection, one of these may be backed up by rifampicin as above.

Vancomycin 1 g i.v. 12-hourly is the most effective substitute for patients who are seriously allergic to penicillins (anaphylaxis or other accelerated reactions) but it is potentially toxic (see below) so that blood levels have to be assayed and the dose adjusted accordingly. Teicoplanin is a less toxic alternative (see below).

Other 'reserve drugs' whose spectra include useful antistaphylococcal activity so that they may be 'added on' in certain circumstances include fusidic acid and aminoglycosides.

### *Treatment of MRSA pneumonia*

The problem of *Staph. aureus* strains no longer susceptible to  $\beta$ -lactamase-resistant antibiotics has become very important. These MRSA strains have appeared in many parts of the world, including Australia, the UK and the USA and are resistant to all  $\beta$ -lactam antimicrobial agents [593]. In the USA they are sufficiently common for intravenous vancomycin to be used as a drug of first choice in any suspected serious staphylococcal infections until the susceptibility of the isolate is known, the dose being 1 g 12-hourly. In the UK the drug may be used 'first off' if the patient with staphylococcal pneumonia is already known to be a carrier of MRSA or if admission has been from a nursing home where MRSA is known to be endemic.

Vancomycin is a glycopeptide that has been clinically available for over 30 years but its use has been limited by toxicity, which is probably one reason why it remains effective. Full MRSA resistance to vancomycin has not been reported thus far. Unfortunately the emergence of intermediate resistance is already taking place [592] as the frequency of this drug's usage increases. Vancomycin-resistant enterococci have also emerged and have spread from intensive care units across hospitals. This is relevant to *Staph. aureus* infection because enterococci may act as a reservoir for vancomycin-resistant genes and this resis-

tance has been shown to be potentially transferable from enterococci to other genera such as staphylococci [594]. Adverse effects to vancomycin include allergic reactions, local phlebitis, flushing ('red man syndrome'), ototoxicity with tinnitus and hearing loss, nephrotoxicity (less common with the purer preparations now available and if other nephrotoxic drugs are avoided) and neutropenia. Dose-related effects may be limited by keeping serum concentrations below 30 mg/L and by using a nomogram in the presence of renal insufficiency. Teicoplanin is a newer glycopeptide antibiotic that may be used instead of vancomycin. It is easier to administer and probably less toxic than vancomycin, with a longer half-life leading to once-daily dosage. It can be used in serious infections as an alternative to vancomycin when allergic reactions or neutropenia have occurred but is expensive. It is usual to add rifampicin to vancomycin or teicoplanin in severe infections, as above.

Tolerance to glycopeptides may occur so that combination therapy may sometimes be required. The choice of combination may be guided by sensitivities and sometimes by microbiological back-titrations of the patient's serum against cultures of the organism [595]. Possible additions include fusidic acid, fluoroquinolones such as ciprofloxacin, minocycline or co-trimoxazole (trimethoprim-sulfamethoxazole) [564,580,596,597].

The management of colonization by MRSA and the prevention of spread within or between institutions is a specialized infection-control area that has been well reviewed [596].

### *Mortality*

The mortality of staphylococcal pneumonia depends upon the virulence of the strain, the age of the patient, the extent of consolidation, the provision of appropriate antibiotics and whether complications such as bacteraemia occur. Before the availability of antibiotics the mortality from staphylococcal bacteraemia stood at about 80% [598]. Even though antistaphylococcal antibiotics are now available, the mortality from this form of pneumonia is still 25–50% overall [165,264,571]. A mortality figure of 75% has been recorded for patients aged over 70 years, higher figures being recorded in bacteraemic cases, compared with 25% for patients aged under 40 years [168,599]. Such younger patients usually fall into the category of postinfluenzal staphylococcal pneumonia of whom an alarming proportion still die despite appropriate antibiotic treatment.

### *Complications*

Staphylococcal pneumonia can itself be a complication of a bacteraemic illness that may become manifest in many ways [566,600]. Some intrathoracic complications have

already been mentioned and include lung abscesses, which occur in 25% of cases (see Chapter 15) and related pneumatoceles. Pneumothorax (see Chapter 44) may occur as a result of focal sepsis rupturing through the visceral pleura. This complication is more likely if mechanical ventilation is required and if the patient is taking corticosteroids for some other reason [601]. When it does occur it is liable to become complicated by infection in the pleural space with resultant pyopneumothorax. Treatment is with continued antibiotics and tube drainage. Empyema may occur in its own right in about 10% of cases [568,570]. Residual pulmonary or pleural shadowing is not uncommon after successful treatment of the pneumonia and its intrathoracic complications.

*Staph. aureus* bacteraemia may be complicated by left-sided endocarditis in about 10% of cases and if this is suspected clinically, treatment should be continued for 4–6 weeks [566]. Patients with known valvular heart disease who develop staphylococcal bacteraemia from any source have a higher risk of developing endocarditis and should be treated as such. Right-sided endocarditis has a lower mortality and usually results from the introduction of venous sepsis such as may occur in heroin abusers. Metastatic abscesses may occur at any site in a bacteraemic case [564]. Profound hypotension (endotoxin shock) may occur in bacteraemia as a consequence of a generalized capillary leak [563]. It may also be complicated by DIC [602]. Cutaneous desquamation or exfoliation is sometimes seen and has already been alluded to [581,582,600]. Rhabdomyolysis has been reported but is seemingly extremely rare [603].

### Prevention

Prevention of all *Staph. aureus* infections in the hospital setting is reduced by simple measures such as handwashing. Infection-control measures include, where possible, the separate nursing of patients who are carriers of MRSA and their treatment with topical agents to eliminate colonization. The same applies to patients with MRSA infection [564,596,597].

### ***Klebsiella pneumonia* (Friedländer's pneumonia)**

The genus *Klebsiella* contains four species, all of which are large, aerobic, non-motile, Gram-negative enteric bacilli. Like *E. coli* they belong to the family Enterobacteriaceae. They have a prominent polysaccharide capsule that is believed to be important in enhancing virulence [604]. Two of these species have been associated with Gram-negative pneumonia, namely *Klebsiella pneumoniae* (Friedländer's bacillus) and less commonly *Klebsiella oxytoca*. These two microbes used to be considered as one species but have been separated in terms of the ability of

the former organism to give an indole-positive reaction and to liquefy gelatin.

### Epidemiology

*Klebsiella* are found in soil, water and in the human faecal flora. *K. pneumoniae* occurs commensally in the oropharynx of 1–6% of healthy people and may be more common in the oropharynx of subjects with carious teeth or periodontal disease [605]. It becomes more prevalent in hospital patients, particularly if they have received antibiotics. It is believed to reach the lungs by aspiration from the oropharynx and certain groups of patients are particularly predisposed. These include alcoholics, diabetics, those who have been endotracheally intubated and those who are elderly or otherwise debilitated by disease [44,606].

### Incidence

*Klebsiella* spp. is the most common group of enteric Gram-negative bacilli to cause community-acquired pneumonia and is also commonly implicated in nosocomial pneumonia [607]. Some series have reported that it accounts for 1–2% of pathogenic organisms isolated in acute pneumonia and for about 8% of those found in more elderly and debilitated patients [165,177,608,609]. *K. oxytoca* is much less commonly cultured from sputum than *K. pneumoniae*, accounting for only 10 of 110 *Klebsiella* isolates in one series [610]. A high incidence of concurrent bronchopulmonary disease has also been reported in *K. oxytoca* infections [610].

### Pathology

*K. pneumoniae* and *K. oxytoca* are unusual among the Gram-negative bacteria in that they may cause a confluent pneumonia of lobar distribution. This led Friedländer in 1882 to suppose that it was a common cause of lobar pneumonia before it was realized that *Strep. pneumoniae* accounted for the majority of these cases.

It is notable that *Klebsiella pneumoniae* tends to involve the posterior segments of the upper lobes and the apical segments of the lower lobes, the majority of cases being unilateral and the right side being affected more frequently than the left. These observations are consistent with the supposition that it is generally caused by the aspiration of the organism from the oropharynx, presumably by patients in the supine position. The affected area of lung becomes distended by viscid oedema fluid that may produce a characteristic radiographic sign (see below). The lung contains an acute inflammatory infiltrate that may result in tissue necrosis and cavitation [474,609]. This necrotizing pneumonia may occasionally cause major vascular compromise resulting in pulmonary gangrene [474].

### Clinical features

The clinical syndrome produced in *Klebsiella* pneumonia may be indistinguishable from that produced by many other acute bacterial pneumonias, except that the infection tends to be severe and, in contrast to other Gram-negative bacteria, may cause a confluent pneumonia of lobar distribution. As with staphylococcal pneumonia, cavitation and abscess formation may occur, although these tend to be less widespread. The sputum is viscid and may be blood-stained, sometimes being fancifully likened to redcurrant jelly.

### Investigations

The Gram stain may be difficult to interpret as *Klebsiella* spp. may be oropharyngeal commensals and irrelevant to any lower respiratory tract infection that may be present. Discussion with the reporting microbiologist may be valuable, as the association of large numbers of organisms with many pus cells is more likely to be significant.

The radiographic features may be variable. A so-called typical case shows confluent shadowing that affects an upper lobe with downward displacement of the fissure, resulting from distension of the lobe with oedema fluid (bowed or bulging fissure sign) [44,611–613]. In reality such classic signs are often absent [614]. Cavitation and necrotizing pneumonia tend to be more evident if the patient undergoes CT [615].

### Treatment

The antibiotic sensitivities of *Klebsiella* spp. are highly variable but resistance to ampicillin is usual. A synergistic combination of an aminoglycoside such as gentamicin with either a third-generation cephalosporin (e.g. cef-tazidime) or an extended-spectrum penicillin such as piperacillin or azlocillin is recommended pending sensitivities [572,616,617]. In hospital-acquired Gram-negative pneumonias, these extended-spectrum penicillins and cephalosporins have the advantage of being active against *Ps. aeruginosa* and other common infecting microbes (see section on core organisms, p. 371). Other antibiotics that may prove effective against *Klebsiella* include the monocyclic  $\beta$ -lactam (monobactams aztreonam, carbapenems such as imipenem/cilastin and meropenem, fluoroquinolones such as ciprofloxacin, co-trimoxazole and chloramphenicol).

Local microbiological guidance should be taken as  $\beta$ -lactamase-producing multidrug-resistant strains of *K. pneumoniae* are endemic in some hospitals [618–620].

### Mortality

The mortality from *Klebsiella* pneumonia is high, at least in

part because it tends to cause disease in elderly or otherwise debilitated patients. Fatality rates as high as 68% have been reported in early series [264].

### Complications

*Klebsiella* pneumonia is complicated by bacteraemia in about 25% of cases [621]. Empyema (see Chapter 14), lung abscesses (see Chapter 15), pleural effusions (see Chapter 43) and other complications may occur as described under staphylococcal pneumonia.

### *Pseudomonas pneumonia*

This is almost always caused by *Ps. aeruginosa* (previously known as *Ps. pyocyaneus*), a Gram-negative, aerobic, motile, flagellate rod that characteristically produces pigments, including pyocyanin. This pigment is green, rather like the colour of verdigris (copper rust), hence the Latin root *aeruginosus*. As well as being flagellate, *Ps. aeruginosa* also possesses fine hairs or pili, with which it may attach itself to epithelial surfaces [622]. Its cell wall is covered by a slimy polysaccharide layer that may protect it from phagocytic attack. It produces various toxins and proteases including an endotoxin that may cause 'shock' in bacteraemia, a phospholipase that attacks surfactant and may produce atelectasis and an elastase that can destroy alveolar septa and which may also be responsible for vasculitis in bacteraemic patients [623,624].

Other members of the genus that occasionally cause pneumonia include *Ps. mallei* and *Ps. pseudomallei* (causes, respectively, of glanders and melioidosis, described below) and also *Ps.* (now *Xanthomonas*) *malophilia* and *Ps.* (now *Burkholderia*) *cepacia*, the cause of onion soft rot and an opportunistic pulmonary pathogen in patients with cystic fibrosis.

### Epidemiology

*Ps. aeruginosa* is an opportunistic pathogen for humans, rarely causing disease in otherwise healthy persons. It occurs naturally in water, soil and vegetable material. Its nutritional requirements are simple, in that it can obtain carbon from carbon dioxide and nitrogen from ammonium and is able to survive in distilled water [625]. The carriage rate for *Ps. aeruginosa* in otherwise healthy members of the community is low, being about 5% for the oropharynx [626,627]. It may also be found in the axillae, anogenital area and in faecal flora [628]. The carriage rate in hospital populations is very much higher and may exceed 50%. The organism has a predilection for moist conditions, and reservoirs of infection may build up in mechanical ventilators, nebulizer equipment, sinks and even in disinfectant solutions (particularly those that contain ammonium compounds) [628]. Hospital

epidemics of pseudomonal infection may occasionally arise from such sources. These high rates of colonization predispose to invasive *Pseudomonas* infection in hospital patients [629] and pneumonia is believed to usually follow the microaspiration of the products of such oropharyngeal colonization into the lungs. Patients particularly at risk include those on mechanical ventilators, those in whom the normal flora are suppressed by antibiotics and those who are in any way immunosuppressed. Pseudomonal infection is a considerable problem in burns patients and the organism may be spread about a ward or unit by hand-to-patient contact [628]. Patients with cystic fibrosis are particularly predisposed to *Pseudomonas* respiratory infections (see Chapter 30) and the organism not infrequently colonizes otherwise chronically damaged lungs.

### Incidence

*Ps. aeruginosa* was found by the National Nosocomial Infections Surveillance System of the Centers for Disease Control to be the commonest cause of hospital-acquired pneumonia, accounting for about 17% of all isolates [140]. It is a less common cause of community-acquired pneumonia, mainly (but not always [630]) affecting elderly or otherwise debilitated members of the population.

### Pathology

Consolidation is usually distributed in a patchy manner and affected areas of lung may contain small abscesses and focuses of haemorrhagic necrosis. These areas may be centred around pulmonary vessels, which may show arteritic changes, this leading to thrombosis with lung necrosis and the surrounding areas of haemorrhage typical of this infection [474,631]. The excised lungs may share the characteristic sweet grape-like smell that characterizes laboratory cultures of *Ps. aeruginosa*.

### Clinical features

*Pseudomonas* pneumonia typically occurs in a patient who is compromised by pre-existing lower respiratory disease of a chronic nature (e.g. bronchiectasis, cystic fibrosis), heart failure, blood dyscrasias or immunosuppressive therapy [632,633]. The organism is all too familiar in intensive care units in association with mechanical ventilation and the previous use of broad-spectrum antimicrobials. At other times it may cause an infective bronchitis, characterized by mucopurulent respiratory secretions in the absence of pneumonic consolidation.

Some cases of *Pseudomonas* pneumonia are associated with bacteraemia [634], others not [635], but in either situation the organism probably first reaches the lungs by oropharyngeal microaspiration. Patients who are neu-

tropenic as a result of chemotherapy are more likely to develop *Ps. aeruginosa* bacteraemia. The infection may be fulminating in bacteraemic cases and may result in endotoxin (septic) shock with hypotension and oliguria. The patient may develop ARDS, with pulmonary oedema occurring as a consequence of a pulmonary capillary leak rather than heart failure, as evidenced by normal pulmonary capillary wedge pressure measurements. Such critically ill patients may also develop DIC. Bacteraemic patients sometimes develop a vesicular rash or erythema gangrenosum, the lesions of which comprise a central area of cutaneous necrosis surrounded by a narrow ring of erythema.

The radiographic features, in common with other pneumonias, are non-specific. Shadowing is frequently patchy and bilateral but more confluent lobar consolidation may also occur. Occasionally the shadowing may be nodular and areas of cavitation or lung abscess formation may be detectable. Small pleural effusions may occur but empyemas are unusual. There may be residual fibrotic changes if the patient survives.

The organism can be grown on standard culture media from sputum or respiratory secretions obtained by some invasive means such as BAL (see above) and its isolation in a clinical setting suggestive of pneumonia calls for appropriate antimicrobial treatment. Blood cultures are positive in less than 10% of cases.

### Treatment

Pneumonia in which *Ps. aeruginosa* is thought to be a causal pathogen is usually treated with a combination of an antipseudomonal  $\beta$ -lactam antibiotic and an aminoglycoside (see section on severe hospital-acquired pneumonia) [141]. There is limited evidence to suggest that this approach produces better results than treatment with a single antipseudomonal agent, potential benefits including increased potency and reduced chances of the emergence of resistant strains [636]. Examples include the antipseudomonal penicillin piperacillin, which has been shown to be more active than azlocillin, mezlocillin, ticarcillin and carbenicillin in this regard [637,638]; an antipseudomonal third-generation cephalosporin such as ceftazidime; a carbapenem such as imipenem/cilastin or meropenem. Gentamicin is a suitable partner and treatment may be continued for 2 weeks in the case of bacteraemic pneumonia or for a shorter period according to response when bacteraemia is not present. A fluoroquinolone such as ciprofloxacin may be used with one of the above  $\beta$ -lactams as an alternative to the aminoglycoside or may be combined with an aminoglycoside in patients who are allergic to penicillin. Such treatment may be modified according to the laboratory sensitivities of the organism since strains of *Ps. aeruginosa* may become resistant to any of the aforementioned drugs by differing

mechanisms, the development of resistance to one class of drug sometimes inducing resistance in another [639]. The treatment of *Pseudomonas* infection in cystic fibrosis, including the topics of antibiotic prophylaxis and nebulization, are discussed in Chapter 30.

### **Mortality**

*Pseudomonas* pneumonia is a severe infection, particularly in association with bacteraemia, and is probably the most lethal nosocomial lung infection, with a mortality of over 60% [264,628,639,640]. It is the most common cause of death in intubated patients with pneumonia [641].

### ***Escherichia coli* pneumonia**

Like *Klebsiella* spp., *E. coli* belongs to the family of Gram-negative enteric bacteria, the Enterobacteriaceae. It is also aerobic but is able to grow in anaerobic conditions (i.e. a facultative anaerobe). Unlike *Klebsiella* spp., it is motile.

### **Epidemiology**

*E. coli* causes a wide range of clinical illness in humans, urinary tract infections and enteritis being the most notable in adult practice. The organism is very much part of the normal gut flora, 1 g of stool containing  $10^8$  organisms [617]. The finding of this organism in the sputum of patients who are ill in hospital need not be clinically significant as the oropharynx is commonly colonized by Gram-negative bacilli in this environment laden with broad-spectrum antibiotics. Nevertheless, *E. coli* is a potential pulmonary pathogen in this group as a result of microaspiration. *E. coli* may also cause pneumonia as a result of haematogenous spread from bacteraemic gut and urinary tract infections, to which diabetics are particularly predisposed. *E. coli* as a cause of pneumonia tends to be confined to elderly or debilitated subjects and this is a point of similarity with other Gram-negative enteric pathogens.

### **Incidence**

Although it is the most common urinary tract pathogen in hospital patients and one of the most common bloodstream isolates, *E. coli* is not a frequent cause of Gram-negative opportunistic bacillary nosocomial pneumonia, being a less common isolate than *Ps. aeruginosa*, *Enterobacter* spp. and *Klebsiella pneumoniae*, and accounts for about 6% of cases [140,607]. It is also an uncommon cause of community-acquired pneumonia, *Klebsiella pneumoniae* being the most common Gram-negative bacillary cause in this group.

### **Clinical features**

The clinical features are those of any bacterial pneumonia. However, sputum may be absent and in the presence of bacteraemia the patient may be prostrated and hypotensive. Clinical features of a primary urinary tract or gastrointestinal tract infection may be evident. The chest radiographic appearances may reflect the haematogenous dissemination of the organism, shadowing often being patchy and bilateral [642,643]. The organism is recoverable from the blood in about 25% of cases [642]; otherwise diagnosis depends upon consistent clinical and radiographic features along with the repeated isolation of the organism from sputum or by some other invasive means of obtaining respiratory secretions such as BAL with quantitative culture (see p. 362). This form of pneumonia is sometimes complicated by empyema.

### **Treatment**

*E. coli* may show considerable strain variation in its susceptibility to antibiotics, and as the prevalence of these strains varies from one hospital to another the choice of antibiotic is likely to be influenced by local considerations. A third-generation cephalosporin such as ceftazidime is usually effective, particularly when combined with an aminoglycoside such as gentamicin, with which synergism occurs [616]. Two antibiotics are preferred because of the serious nature of Gram-negative pneumonia but treatment may be modified according to clinical response and full laboratory sensitivities.

### **Mortality**

The mortality is generally reported to be high and this is in part because patients frequently have serious coexisting disease, as is often the case with other Gram-negative pneumonias [43,264]. Fatality rates of about 30% have been reported for *E. coli* pneumonia in the past [264,643], although the impact of this organism on the mortality of ventilator-associated pneumonia is thought by others to be marginal [641].

### **Pneumonia caused by other Gram-negative aerobic opportunistic bacilli: *Enterobacter*, *Serratia*, *Proteus*, *Acinetobacter***

Apart from *Klebsiella* spp. and *E. coli*, a number of other genera in the Gram-negative family Enterobacteriaceae have been causally related to cases of pneumonia either in elderly or otherwise sick and debilitated patients. These include *Enterobacter* spp., *Serratia marcescens* and *Proteus* spp. All are opportunistic lower respiratory tract pathogens, producing disease as a result of the microaspiration of oropharyngeal contents.

*Enterobacter* spp. are more common nosocomial respiratory pathogens than was previously thought, accounting for about 11% of hospital-acquired respiratory infection [140]. These opportunists can be spread between patients on the hands of staff and frequently colonize patients who have been treated with broad-spectrum antibiotics, particularly those on intensive care and burns units. The most common hospital opportunist in this genus is *Enterobacter cloacae*. This group of organisms commonly produce  $\beta$ -lactamases so that it is usual to treat with combined  $\beta$ -lactam/aminoglycoside therapy [644].

*Serratia marcescens* is a less common colonist of the adult gastrointestinal tract than other Enterobacteriaceae and is more likely to be found in the respiratory or urinary tracts of hospital patients. It can be spread on the hands of hospital staff and may be responsible for about 4% of hospital-acquired lower respiratory tract infections [645]. Such infection has been associated with instrumentation of the respiratory tract and the use of contaminated respiratory therapy equipment [646]. About 5% of strains of *Serratia marcescens* produce a reddish pigment called prodigiosin, which may discolour respiratory secretions and be mistaken for haemoptysis. It is usual to treat such cases as for *Klebsiella* or *E. coli* pneumonia, but therapy may have to be modified in the light of multidrug resistance [647].

*Proteus* spp. are highly motile, flagellate bacteria that reside in the gastrointestinal tract but which may cause opportunistic infection in the urinary and, less commonly, respiratory tracts of debilitated patients. Most infections are due to *P. mirabilis* and some to *P. vulgaris*. Antimicrobial treatment is along the lines described for *Klebsiella* spp. but may need modification in the light of sensitivities.

*Acinetobacter* is a genus of free-living, Gram-negative, non-motile coccobacilli belonging to the family Neisseriaceae. It is a common cutaneous colonist, particularly among hospital personnel, and may also colonize the oropharynx of 7% of healthy people [627]. It has a predilection for intensive care units and frequently colonizes tracheostomy sites. It may cause outbreaks of nosocomial pneumonia in this environment, particularly in sick patients who have been treated with broad-spectrum antibiotics [648]. It reportedly causes 3% of cases of hospital-acquired pneumonia in North America [649]. This form of pneumonia has also been acquired in the community and may have a predilection for alcoholics [650]. A small outbreak of *Acinetobacter* pneumonia has been described in iron foundry workers, raising the possibility that dust exposure increased the susceptibility of these subjects to infection by this organism [651,652]. *Acinetobacter* pneumonia has no particular features to distinguish it from pneumonia caused by other Gram-negative opportunistic bacilli except that bacteraemia is said to be unusual. If bacteraemia does occur it may be complicated by hypotension, as is the case with

other Gram-negative organisms [653]. The treatment options are broadly similar to those outlined for *Ps. aeruginosa* above.

### ***Haemophilus influenzae* pneumonia**

*H. influenzae* is a small, non-motile, Gram-negative, aerobic, pleomorphic coccobacillus that may assume filamentous form. It is a strict parasite of humans, with no other natural hosts and occurs in both encapsulated and non-encapsulated forms. The encapsulated group may be serotyped in terms of capsular polysaccharide into types a–e, type b being that which causes invasive infection most frequently, usually in young children in whom it may produce bacteraemia with meningitis, epiglottitis, cellulitis, septic arthritis and sometimes pneumonia. The other five encapsulated types are rarely pathogenic. The non-encapsulated (or non-typable) forms are usually responsible for the more common adult respiratory tract infections with which we are concerned in this section.

### **Incidence**

Pfeiffer in the nineteenth century wrongly believed *H. influenzae* to be the cause of influenza, hence its specific name. Doubt and uncertainty persist about the frequency with which *H. influenzae* causes pneumonia and it is more commonly associated with purulent exacerbations of chronic bronchitis. Such uncertainties are fuelled by the frequency with which the organism occurs in the respiratory tract not only in patients with lower respiratory tract disease other than pneumonia but also in health, so that isolation of the organism in sputum has to be viewed critically. Unencapsulated forms are commonly retrievable from the pharynx but not the lower respiratory tract of fit adults and children and in the mucoid sputum of up to 60% of chronic bronchitics [44]. Encapsulated forms are less commonly carried, being found in up to 6% of healthy subjects [44,643]. The belief has been held that encapsulated strains have usually been responsible for pneumonia, although non-encapsulated forms have also been implicated in both bacteraemic and non-bacteraemic pneumonia [44,654–656]. Spread is by droplet nuclei or other contact with respiratory secretions and lower respiratory tract infection is believed to arise as a result of the microaspiration of the organism from the pharynx.

A study of community-acquired pneumonia carried out in Nottingham ascribed a causative role to *H. influenzae* in 3% of 127 patients [167], and the British Thoracic Society multicentre trial found it to be an aetiological factor in 6% of cases [35]. Series in which the diagnosis is based on sputum isolation overestimate the frequency of *Haemophilus* pneumonia and those purists who accept the

diagnosis only following culture from blood, protected tracheobronchial samples, pleural fluid or direct lung puncture might be expected to underestimate, although a recent Danish study of 254 patients with community-acquired pneumonia isolated *H. influenzae* from transtracheal aspirates in 16 cases and found this organism to be causal in approximately 17% of pneumonias in previously healthy individuals under 50 years of age [657]. Positive cultures from transtracheal aspirates in patients with chronic bronchitis need not be diagnostically valid as *H. influenzae* tends to colonize the trachea in these subjects [658]. *H. influenzae* has been reported in about 6% of cases of nosocomial pneumonia [140].

### *Clinical features*

The onset of *H. influenzae* pneumonia may be more insidious than is usually seen with other acute pneumonias such as that caused by *Strep. pneumoniae*. It usually but not invariably occurs in patients, often elderly, with exacerbations of underlying lung disease, such as chronic bronchitis or asthma, commonly following viral upper respiratory tract infection. It may also occur in association with alcoholism or in patients with impaired immunity, including those with HIV infection [659,660]. There are no specific radiographic findings. Shadowing may be patchy or more confluent and in some cases is lobar [655,661].

Laboratory identification of the organism by Gram staining and culture is not usually difficult. Culture techniques may be applied to specimens of sputum, blood and on occasions pleural fluid or other invasively obtained specimens. The development of techniques to enable more rapid detection of encapsulated forms by the recognition of capsular polysaccharides using counter immunoelectrophoresis (CIE) and other methods have been described [662,663].

### *Treatment*

Although the majority of strains of *H. influenzae* are sensitive to the aminopenicillins amoxicillin and ampicillin, there is concern about the increasing emergence of resistant forms that produce  $\beta$ -lactamases. A survey carried out in the UK in 1981 showed 6.2% of isolates to be resistant to ampicillin [664]. The incidence of strains resistant to ampicillin/amoxicillin in the UK continues increase, rates of 8–15% having been reported across the country, with much higher rates in Spain and the USA so that it is essential to be informed about the sensitivity patterns in ones own locality [121,665,666]. Second- and third-generation cephalosporins such as cefuroxime and cefotaxime are highly active against *H. influenzae* and may be used parenterally in serious infections pending the results of sensitivities, after which treatment may be modified

accordingly [666,667], ampicillin or amoxicillin being the drugs of choice for those susceptible strains that still form the majority. Other effective agents include co-amoxiclav, clarithromycin or azithromycin, fluoroquinolones such as ciprofloxacin, third-generation cephalosporins and extended-spectrum penicillins. Chloramphenicol is usually effective but should rarely be used, particularly when reliable alternatives for severe infection such as cefotaxime are available (see Chapter 9).

By virtue of its polysaccharide capsule, *H. influenzae* type b conjugated vaccines have been developed, their use having been confined to paediatric practice, where this organism is a major cause of morbidity and mortality, largely from meningitis, epiglottitis and pneumonia [668]. Whether or not such vaccines might have an important preventive role in respiratory infection in developing countries, where invasive capsular strains other than type b may be endemic, is not known [18,669].

### *Moraxella catarrhalis pneumonia*

*Moraxella* (previously *Branhamella*, previously *Neisseria*) *catarrhalis* has long been known to live commensally in the oropharynx and was largely ignored as a potential lower respiratory tract pathogen until a spate of reports of significant isolates obtained mostly from patients with coexisting and often chronic lung disease [670–675]. Such isolates are usually found in exacerbations of chronic bronchitis, and *Moraxella* pneumonia is quite unusual, probably accounting for 1–3% of cases of community-acquired pneumonia [121]. It has been described in the immunocompromised and in elderly patients with underlying chronic pulmonary disease, who are particularly susceptible to *M. catarrhalis* infection [676–678]. *M. catarrhalis* is a Gram-negative, aerobic coccobacillus that is a member of the Neisseriaceae family and was known by that name until 1970, when it was given its own genus because of various biochemical and antigenic differences [679]. As an upper respiratory tract pathogen it may cause both sinusitis [680] and acute laryngitis [681] and may extend directly to cause otitis media [682].

The organism is carried in the upper respiratory tracts of about 50% of children, 5% of adults up to the age of 60 years and 25% of people over this age, so that the significance of isolates of *M. catarrhalis* in the sputum has been a subject for debate [683,684]. However, it has become increasingly accepted that a moderate or heavy growth obtained from mucopurulent sputum containing Gram-negative coccobacilli and neutrophils may be clinically important, justifying therapeutic intervention [670,671]. In addition to purulent bronchitis, patchy consolidation may occur.

The reason for the appearance of pathogenic strains is unclear but the frequency with which ampicillin is

prescribed may have encouraged the emergence of  $\beta$ -lactamase-producing forms [671]. Lower respiratory tract infection is believed to arise as a result of the aspiration of the organism from the oropharynx. Bacteraemia is highly unusual [685]. The organism can survive drying and nosocomial infection may occur, cross-infection within a respiratory unit having been confirmed by DNA studies [671,686].

Upwards of 80% of *M. catarrhalis* isolates are  $\beta$ -lactamase producers and are therefore resistant to ampicillin/amoxicillin [671,687,688]. The organism is usually sensitive to macrolides, co-amoxiclav (amoxicillin-clavulanic acid) and ampicillin-sulbactam (USA), second- and third-generation cephalosporins, fluoroquinolones such as ciprofloxacin, as well as tetracycline and cotrimoxazole but is resistant to trimethoprim alone.

### **Pneumonia caused by anaerobes (including aspiration pneumonia)**

The incidence of anaerobic pneumonia is uncertain because it may go undiagnosed unless the suspicions of a physician are raised by the presence of a lung abscess (see Chapter 15), the development of an empyema (see Chapter 14) or a history of either witnessed aspiration or more frequently of presumed aspiration in a predisposed host. It is likely that many cases never come to microbiological diagnosis as most anaerobes are susceptible to a variety of antibiotics, including penicillin, and are dealt with by early antimicrobial treatment.

#### **Pathogenesis**

Anaerobic pneumonia occurs as a result of aspiration. The oropharynx is particularly favoured by anaerobes which multiply there commensally, prodigious quantities of them being found in saliva ( $10^8$ /mL in healthy people, increasing 1000-fold in the presence of dental sepsis), where they outnumber aerobic organisms by 10 to 1 [399]. Radioactive tracer techniques have been used to show that small amounts of saliva are aspirated into the lungs during sleep in 45% of healthy people and in 75% of patients whose level of consciousness is depressed for various reasons [689].

A predisposing factor can be found in the majority of patients in whom anaerobic infection is identified. These factors include conditions in which the cough reflex is lost or depressed, such as alcohol, hypnotic or other sedative drug overdosage, neurological disease including strokes, epilepsy and bulbar palsy, general anaesthesia and other causes of depressed conscious level such as diabetic coma [690]. Any of these situations may cause some of the stomach contents to be aspirated, the low pH of which can cause a chemical pneumonitis that may well predispose to bacterial infection [691]. Conditions that

result in oesophageal obstruction (Fig. 13.15) as well as gingival and chronic sinus infections also predispose.

The organisms found to be responsible for anaerobic lung infections occur in the same relative proportions to those found in the mouth, this tending to corroborate the supposition that aspiration is the source of the infection [689]. The main groups of anaerobes include the following.

- 1 Gram-negative bacilli making up the genus *Bacteroides*, notably *Bacteroides fragilis*. To add to the clinician's difficulties, the taxonomists have consigned some strains of what used to be called *Bacteroides melaninogenicus* to two newer genera, *Prevotella* and *Porphyromonas*.
- 2 Gram-positive cocci, mainly *Peptostreptococcus* and anaerobic or microaerophilic streptococci.
- 3 Long thin Gram-negative rods comprising *Fusobacterium* spp., particularly *F. nucleatum* and *F. necrophorum*.

The likelihood of pneumonia developing following aspiration is probably influenced by the quantity, bacterial content and pH of the material aspirated, and the quality of the patient's lung defences. The latter includes both mechanical clearance and cellular and humoral competence, patients taking corticosteroids or immunosuppressives being more vulnerable. Finally the presence of coexisting lung disease and the speed with which infection is recognized and treated appropriately are clearly relevant.

A pH of less than 2.4 has been shown to produce lung injury in animal models, and in cases of massive aspiration chemical lung injury rather than infection may be the main problem, producing diffuse alveolar infiltrates and sometimes leading to ARDS [692].

#### **Clinical features**

Cases of aspiration pneumonia acquired in the community are likely to be predominantly anaerobic [693]. Their clinical manifestations may differ from those of other forms of acute pneumonia in that the infection may be rather more insidious and the fever less pronounced, with malaise, weight loss and a cough sometimes productive of foul-smelling sputum.

Nosocomial cases may differ in that the oropharyngeal flora of these patients is likely to have been modified by their hospital stay and by previous broad-spectrum antibiotic treatment, so that in this situation anaerobes are more likely to contribute to a mixed pulmonary infection, which may also contain Gram-negative organisms (e.g. *Ps. aeruginosa*, *Acinetobacter*, *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus* spp., *E. coli*) and *Staph. aureus*, in which case the pneumonia is likely to be necrotizing and more severe. Any case of aspiration pneumonia may become complicated by lung abscess or empyema (see Chapters 14 & 15).

Cases of witnessed aspiration with chemical lung injury due to low pH may develop respiratory distress due to

pulmonary oedema within minutes and require urgent respiratory support.

### Diagnosis

Radiographic features suggestive of aspiration include unilateral or bilateral pneumonic infiltrates or abscess cavities, typically in the apical segments of either or both lower lobes or in the posterior segment of the right upper lobe, these being the segments most susceptible to aspiration by virtue of their dependent position in subjects who are lying supine (see Fig. 15.2) [694]. Abscess cavities may be large with fluid levels (see Figs 15.4, 15.5 & 15.7) or small with multilocular areas of rarefaction indicating so-called necrotizing pneumonia [695]. A complicating pleural effusion or empyema may be present. Massive aspiration of acid stomach contents may produce pulmonary oedema and ARDS and particles of food may sometimes physically obstruct a bronchus causing persistent distal infection.

Anaerobic infection may be suspected when a variety of Gram-positive cocci and Gram-negative rods are seen under the microscope in a purulent sputum sample that produces no growth on aerobic culture. Precise microbiological diagnosis is difficult in the absence of a readily accessible and uncontaminated pool of infection, such as may be provided by the presence of a complicating empyema. Anaerobic sputum culture is worthless as it is bound to be contaminated by oral commensals. Similarly, any specimen that has been obtained by the passage of a conventional suction catheter or bronchoscope through the mouth is certain to have become contaminated by anaerobic oropharyngeal commensals. When anaerobic infection is thought to be a real possibility, these difficulties may be overcome by transtracheal aspiration, a technique that has been much written about but which is seldom used by practising physicians (see Chapter 8) [69,690]. Oropharyngeal contamination can also be avoided by the passage of a protected specimen brush (PSB) through a specially designed catheter which is in turn introduced through the fiberoptic bronchoscope [70]. Finally when infection is localized, the area of interest may be sampled by percutaneous ultra-thin needle aspiration (see p. 362 and Chapter 8) [79]. Close cooperation with the microbiology laboratory is essential before any such specimens are taken so that they can be received promptly, as anaerobes are particularly fastidious and perish within an hour of exposure to air [696].

**Fig. 13.15** (a) Patchy areas of consolidation in right upper and mid zones and behind left hilum. (b) Barium swallow in same patient showing achalasia of the cardia, responsible for recurrent aspiration. (c) Upper lobe fibrosis and bronchiectasis and left lower lobe consolidation in patient with recurrent aspiration over many years from pharyngeal pouch.

Blood cultures, although carried out routinely in pneumonia, are not usually helpful in isolating anaerobic organisms as bacteraemia occurs in only 2% of cases.

Gas-liquid chromatography has been described as a rapid method for the identification of anaerobes in expectorated sputum, producing a result in less than 1 h and being capable of making a distinction between lower respiratory tract infection and contamination by commensals. This technique detects the presence of the volatile fatty acids that account for the characteristically putrid smell associated with specimens in which anaerobes are contained. The report found no false-positive results but the equipment is expensive and not widely available [697].

### Treatment

An accurate microbiological diagnosis in cases of suspected aspiration pneumonia may prove elusive, as mentioned above, so that the choice of antimicrobial is often based on probability. Community-acquired cases are usually caused by anaerobes. Although penicillin is active against the majority of anaerobes, a significant number of strains, including members of the *Bacteroides fragilis* group, are now resistant as a result of  $\beta$ -lactamase production [698]. These may be dealt with by the addition of metronidazole, which should not be used alone as some anaerobic cocci and most microaerophilic streptococci (e.g. *Strep. milleri/intermedius*) are resistant to it. This may lead to a significant number of treatment failures if the drug is used as monotherapy, whereas these organisms are dealt with if penicillin is used in partnership with it [699]. Two prospective randomized trials have compared benzylpenicillin with clindamycin, which is active against *Bacteroides fragilis* and other penicillin-resistant anaerobes as well as having some activity against *Staph. aureus* [700,701]. Both of these studies showed that clindamycin did better than penicillin in terms of lysis of fever and clearing of sputum, with fewer treatment failures and relapses. Although potentially more toxic, clindamycin may be used singly as a substitute for penicillin and is certainly a rational choice in a patient who is allergic to penicillin. Its most serious limiting side-effect is pseudomembranous colitis.

Many other antimicrobial agents are active against anaerobes *in vitro* but have not been subjected to clinical trials in patients with lung abscess, largely because of the relative infrequency of this type of sepsis and because of the meticulous nature of trial-regulating agencies who require microbiological proof of the responsible organisms. These apparently effective antibiotics include most but not all  $\beta$ -lactams and activity is particularly augmented by combination with a  $\beta$ -lactamase inhibitor, as in the case of amoxicillin and clavulanic acid (co-amoxiclav). Similarly, in the USA, ampicillin is available in combination with the  $\beta$ -lactam inhibitor sulbactam.

When aspiration pneumonia is hospital-acquired, Gram-negative aerobic bacilli should also be covered and the possibility of staphylococcal infection, which may also be present following aspiration, should be considered [572]. Antimicrobials with activity against both anaerobes and Gram-negative aerobic organisms include the extended-spectrum (antipseudomonal) penicillins such as the ureidopenicillins piperacillin, azlocillin and mezlocillin (not available in the UK) and the carboxypenicillins ticarcillin and carbenicillin (not available in the UK) and may be appropriate for hospital-acquired cases. Ticarcillin is also available in combination with the  $\beta$ -lactamase inhibitor clavulanic acid.

Imipenem, which is a carbapenem  $\beta$ -lactam, has excellent *in vitro* activity against anaerobes as well as being active against a wide spectrum of Gram-positive and Gram-negative bacteria including *Ps. aeruginosa*.

Of the cephalosporins, cefoxitin (considered second generation but in fact a cephamycin) is the most potent *in vitro* against the *Bacteroides fragilis* group, tending to be relatively resistant to  $\beta$ -lactamases produced by Gram-negative bacilli. Third-generation cephalosporins, for example ceftazidime, and related drugs are less active against anaerobes.

The management of anaerobic lung infections should include measures directed to the removal of the cause wherever this is possible.

Tachypnoea and hypoxia resulting from low pH lung injury due to massive witnessed aspiration require appropriate airway management and respiratory support. This may include endotracheal intubation and mechanical ventilation when complicated by ARDS. Corticosteroids have no role to play in this situation, which may become complicated by bacterial infection. Atelectasis may raise the suspicion of particulate airway obstruction, in which case bronchoscopy is indicated.

## Viral pneumonias

### Influenza virus pneumonia

Although this infection is usually benign it may be complicated by primary viral or more commonly secondary bacterial pneumonia, which may either follow in the wake of influenzal infection or which may occur simultaneously. A minority of cases with clinical evidence of pneumonia show no evidence of bacterial superinfection and a pure viral aetiology is assumed [702]. The frequency with which this occurs is uncertain but it is likely that influenzal pneumonia is the most common of the viral pneumonias. There is evidence to suggest that it occurs more often in patients with underlying heart disease [703]. It was noted that half the women of child-bearing age who died in the 1957 influenza epidemic were pregnant [704], suggesting that this condition increased their susceptibility to compli-

cating pneumonic infection [705]. It is usual for postinfluenzal pneumonia to occur during seasonal epidemics between October and April.

The syndrome of primary influenzal pneumonia, in common with other viral pneumonias, may vary greatly in severity. At one end of the scale the patient may have relatively few pneumonic symptoms and signs and little radiographic shadowing. More severe cases progress from the typical influenzal syndrome, so that in addition to fever and cough the patient becomes increasingly breathless and cyanosed with widespread crackles, usually in the absence of the classical signs of consolidation. The chest radiograph may show diffuse patchy pulmonary infiltrates. The sputum does not yield pathogenic bacteria and antibiotics are ineffectual.

In addition to inflammation and necrosis of the tracheobronchial epithelium, the pathological changes may also show an intra-alveolar haemorrhagic exudate containing many mononuclear cells.

Bacterial pneumonia as a secondary complication of primary influenzal infection may produce an apparent relapse, following a typical influenzal type of illness, in which fever recurs and mucopurulent sputum may be expectorated. The general principles of supportive treatment of any pneumonia apply and as the organisms involved are usually *Strep. pneumoniae*, *Staph. aureus* or *H. influenzae* [706,707] initial antibiotic treatment during influenza epidemics should be tailored to cover infection by these three bacterial pathogens.

Other aspects of influenzal infection are discussed in Chapters 9 and 12.

### Measles virus pneumonia

Measles is caused by a paramyxovirus belonging to the genus *Morbillivirus*. The measles virus produces a very highly contagious infection that in unvaccinated populations typically afflicts young children. Countries with active vaccination programmes have virtually eradicated the disease but outbreaks increasingly occur in older adolescents or adults who were not vaccinated in childhood and who escaped contact until later life [708]. The disease is spread worldwide and may occur at any time of the year, although most episodes are diagnosed in the winter or spring.

The virus is spread by respiratory droplets. The incubation period is about 10 days, after which a febrile illness occurs with conjunctivitis, rhinitis and cough. Koplik's spots may appear as small white punctate lesions on the buccal mucosa opposite the molars and precede the widespread maculopapular rash by a day or two. Immunocompromised patients sometimes show no rash.

The virus can invade the whole of the respiratory mucosa and may be complicated by pneumonia. This may be primary viral pneumonia or secondary to bacterial

infection, the most common organisms being *Strep. pneumoniae*, *Staph. aureus*, *H. influenzae* and *Neisseria meningitidis* [709–711]. It is difficult to determine the true prevalence of primary measles pneumonia as respiratory symptoms are universal in measles. The reported rate of measles pneumonia in military recruits has varied widely, falling between 3 and 50% depending on the diagnostic criteria used [711]. The severity of measles pneumonia may range from a mild infection to a severe illness, fatalities occurring particularly in young malnourished children or in those who are immunocompromised. Fatality is rare in immunocompetent adults [712]. The clinical findings do not differ significantly from other viral pneumonias including those due to influenza. There may be rhinitis, a dry cough, tachypnoea and hypoxaemia. The chest radiograph usually shows diffuse infiltrates. Coalescence of these lesions into nodules has been described [713].

The syndrome of atypical measles has been described, mainly in patients who had been previously immunized with killed measles vaccine prior to the advent of live measles preparations. The illness is assumed to result from a hypersensitivity reaction to wild measles virus in subjects who possess only partial immunity. It has occurred mainly in young adults or adolescents. The rash is modified and may include petechiae. It starts peripherally and then moves to the trunk, which is the opposite of what occurs in classical measles. Furthermore, rhinitis, conjunctivitis and Koplik's spots may not be seen. Pneumonia is common and pulmonary radiographic infiltrates, which may be persistent, are described in the majority of cases [713]. There may also be hilar lymphadenopathy [714].

The diagnosis of measles is based on the clinical findings and may be confirmed by a fourfold rise in the titre of measles antibody between acute and convalescent serum samples. Measles antigen can be detected by indirect immunofluorescence and an appropriately equipped laboratory can grow the virus in human kidney or monkey cells.

No specific treatment exists for primary measles pneumonia and management is supportive. Secondary bacterial infection is treated with antibiotics to cover the three most likely causative organisms and may be modified in the light of culture results. Prevention is by live attenuated vaccine but this form of immunization should not be used in pregnancy or given to immunocompromised patients, who may be protected by immunoglobulin if given within 72 h of exposure [714].

### Adenovirus pneumonia

Adenoviruses, so named because of their original isolation from human adenoid tissue, are most noted for their capacity to cause respiratory infection and conjunctivitis.

They are transmitted by droplet spread, the faecal–oral route and fomites. They are responsible for about 10% of all respiratory disease in children [715] and although these infections are usually minor, fatal pneumonia may occur and has been described in epidemic form [716]. The incubation period is between 2 days and 2 weeks. Adenoviruses may cause acute tracheobronchitis in adults and epidemics have been described in military bases [717,718], a few cases having been pneumonic and fatal [719,720]. Such episodes occur more frequently in adults than in the paediatric age group and immunocompromised patients are more susceptible [721]. There over 40 serotypes and several may cause lower respiratory tract disease, types 3, 4, 7b, 14 and 21 being among the most important in this regard, although other serotypes may be responsible in immunocompromised patients [714,722].

There are no particular clinical features to reliably distinguish adenovirus pneumonia from other viral pneumonias. The patient feels unwell with a fever, sore throat and cough and may also have conjunctivitis. Lymphopenia may be present but this finding cannot be relied upon. The chest radiograph may show focal infiltrates or more widespread shadowing and is not diagnostic. The presence of a pleural effusion has been described. The organism may be recovered from pharyngeal swabs and has been found in the lungs at postmortem when tissue culture techniques have been applied [719]. Diagnosis is often based on clinical and epidemiological considerations or is retrospective, usually relying upon CFT to detect a fourfold increase in antibody titres between acute and convalescent serum samples [723].

Live attenuated adenovirus vaccines that may be taken orally have been used with good effect in military personnel but are not generally available [718,724]. Treatment is supportive and serious sequelae are unusual in immunocompetent patients. The apparently successful use of intravenous tribavirin (ribavirin) and pooled normal human immunoglobulin has been reported in a case of severe adenoviral pneumonia affecting an immunosuppressed patient [725].

### Chickenpox pneumonia

Chickenpox or varicella is an almost universal and usually mild infection of early childhood. Pneumonia is rarely seen as a childhood complication but may occur in up to one-third of adult cases [726]. A prospective study of military recruits found radiographic abnormalities in 16% of those who developed varicella but only 2% of these subjects became short of breath [727]. Relatively few adults are susceptible to chickenpox, the majority having acquired immunity as a result of childhood infection. Those who have not may contract the disease, usually from children. It has been suggested that tobacco smokers may be more likely than non-smokers to develop chicken-

pox pneumonia and an association with pregnancy has been noted [728,729].

Both herpes zoster and varicella are caused by the same herpes virus known as varicella-zoster virus (VZV), herpes zoster being caused by a reactivation of latent infection. The incubation period for varicella infections is about 2 weeks and patients are infectious for a few days after the appearance of the rash.

Varicella is a febrile illness and is accompanied by an erythematous centrifugal rash with superficial vesicles that crust. Pneumonia may be accompanied by a cough, shortness of breath and sometimes by pleuritic pain. Haemoptysis may occasionally occur. Adults who develop symptomatic chickenpox pneumonia may become severely ill, with tachypnoea and hypoxaemia [730]. Despite the presence of respiratory symptoms, there may be no notable auscultatory findings. Immunocompromised patients are more likely to develop severe disease, with secondary bacterial infection and ARDS [731,732]. Dissemination of the virus to the lungs in patients with herpes zoster (shingles) caused by reactivation of VZV infection is rare.

The diagnosis is based on the finding of a typical rash in a patient with a history of varicella contact. The chest radiograph may show patchy or diffuse bilateral alveolar-type shadowing that may progress rapidly. Hilar lymphadenopathy and pleural effusions occasionally occur. The disease is usually self-limiting, radiographic improvement occurring over the space of a few weeks. It may later result in nodular calcific shadowing scattered throughout both lung fields (Fig. 13.16), this being an occasional incidental finding on a routine chest film that results in a retrospective diagnosis of earlier chickenpox pneumonia [733].

Herpes-like virus particles may be identified in vesicle fluid and respiratory secretions under electron microscopy. A rapid direct immunofluorescent antigen test can be carried out on cell scrapings [714]. The organism can be cultured on cell lines by a virus laboratory but the diagnosis is more usually made clinically, with retrospective confirmation, if required, by the demonstration of a fourfold or greater rise in varicella antibody titre from serum samples or by indirect immunofluorescence, ELISA and neutralizing antibody testing.

Treatment of chickenpox with aciclovir (acyclovir; see Chapter 9) has been shown to shorten the illness in children [734]. There have been no such controlled trials of this agent in varicella pneumonia but case reports imply it is effective [735]. This form of treatment is justifiable because of the significant mortality rates (20–40%) reported from cases ill enough to require hospital admission [730,736]. This drug has also been used in pregnant women with VZV pneumonia [735]. It is conventional to use a higher dose in immunocompromised patients [714,730]. Broad-spectrum prophylactic antimicrobial

(a)

(b)

**Fig. 13.16** (a) Extensive bilateral consolidation in previously well 30-year-old woman with severe varicella pneumonia. The patient recovered with oxygen and supportive therapy. (b) Bilateral small rounded calcified lesions of healed varicella pneumonia.

treatment may be used in this group of patients to cover both Gram-positive and Gram-negative organisms because of the higher risk of superadded bacterial pneumonia. Chickenpox is highly contagious and primary herpes zoster infection may also be acquired from patients with shingles by direct contact, a risk that largely applies to susceptible staff [737]. The patient should be isolated to protect immunocompromised subjects from exposure where possible. VZV immunoglobulin has been used as passive prophylactic immunization and may be effective if given to susceptible patients within 4 days of exposure, but is thought to be ineffective once the disease is established [714]. Trials of varicella vaccine are being carried out but its efficacy in immunosuppressed adults has not yet been demonstrated [738].

### Cytomegalovirus pneumonia

Cytomegalovirus (CMV) belongs to the herpes virus group as do herpes simplex, VZV and Epstein–Barr virus. Latent infection and reactivation may occur, as is the case with other members of the herpes virus group. Serological evidence of previous CMV infection is very common in communities as a whole, ranging between 40 and 100%, the higher prevalence figures tending to be found in developing countries [739]. Transmission appears to be by contact with body fluids and may occur in the perinatal period as well as by sexual contact, blood transfusion and organ transplantation.

Infection by this virus is usually inapparent and associated disease in immunocompetent subjects is rare. It may cause a syndrome of heterophile negative mononucleosis (Paul–Bunnell negative glandular fever) [740], in which the patient may become febrile with malaise and palpable lymphadenopathy. Atypical lymphocytes may also be found in the blood film and there may be mild abnormalities of liver function. Reports of CMV pneumonia in otherwise healthy adults are rare [741]. Such infection is usually mild and self-limiting and is characterized by the finding of diffuse pulmonary infiltrates on the chest radiograph.

In contrast to this, CMV is important as a respiratory pathogen in adult practice mainly as the commonest viral cause of pneumonia in immunocompromised patients and as such is discussed in Chapter 52. It is of particular importance in the recipients of organ transplants and in those with AIDS [742,743]. The likelihood of CMV pneumonia in organ transplantation is related to the degree of immunosuppression, with a higher incidence having been reported in older regimens that relied on bigger doses of corticosteroids [744]. Seronegative recipients receiving organs from seropositive donors are at greater risk, so that transplant units may take steps to avoid this situation arising [745]. The role of CMV in cases of pneumonia in immunosuppressed patients is not always clear as it has been recovered from the lungs of patients with no overt

evidence of pulmonary disease and at other times may be one of a number of other mixed bacterial and fungal pathogens, including mycobacteria and *Pneumocystis carinii*. At other times it may itself be responsible for a fulminating pneumonia [714].

Serology is unhelpful in diagnosing CMV pneumonia, which relies upon the histological demonstration of typical intranuclear inclusion bodies in BAL fluid and transbronchial biopsy specimens in a patient with a consistent clinical picture [474].

The risk of CMV pneumonia can be reduced if the use of CMV-positive blood products is avoided in seronegative immunosuppressed patients. Treatment is with either intravenous ganciclovir or foscarnet (see Chapter 9). The former may cause myelosuppression, especially if given with aciclovir, and the latter renal toxicity. Valacyclovir, an oral prodrug of acyclovir, has been shown to provide effective prophylaxis against CMV infection in groups of immuno-suppressed patients [745].

### Miscellaneous viral pneumonias

There are occasional reports of adult pneumonia occurring in association with other respiratory viral infection, including those caused by coronaviruses [746], Coxsackieviruses [747], parainfluenza viruses [748], rhinoviruses [749] and RSV [750]. RSV is a common cause of lower respiratory infection in infants and is the commonest cause of pneumonia in children under 3 years of age [751]. It may cause a benign upper respiratory tract infection in young adults, occurring in the winter months, and in old age may cause an influenza-like illness or bronchitis that has been associated with pneumonia [752]. RSV can be treated with ribavirin in children but there are no data showing that this is effective in adults. There have also been reports of pneumonia caused by Epstein–Barr virus in patients with infectious mononucleosis [753]. Herpes simplex virus rarely causes pneumonia in previously healthy subjects but may do so in immunocompromised hosts [754,755].

### Hantavirus pulmonary syndrome

In 1993, a previously unidentified North American hantavirus was identified as the infective agent responsible for an initially small outbreak of severe and often fatal respiratory illness, mainly affecting previously healthy young adults many of whom were ethnic Navajos living in a remote rural area of the south-western USA known as the Four Corners [756,757]. The illness was characterized by a short prodromal phase of headache, malaise, myalgia, nausea and abdominal discomfort, during which thrombocytopenia was sometimes found. This was followed by the rapid onset of ARDS and circulatory collapse. The virus, which was later named hantavirus Sin Nombre (SN), belongs to a genus distributed globally, each

species being carried by a different rodent, the reservoir for SN being the North American deer mouse and the virus transmitted to humans by the inhalation of dried deer mouse excreta. Elsewhere in the world, such as Europe and the Far East, other hantavirus species may cause forms of 'haemorrhagic fever and renal syndrome' with varying degrees of thrombocytopenia and renal insufficiency but without any pronounced respiratory symptoms. Over 100 cases of hantavirus pulmonary syndrome have been recorded mainly in the southern USA and the mortality rate has been about 50%. The organism was identified by specific antibody reactivities in the serum and by using a reverse transcriptase PCR. Pathological changes include pleural effusions, gross intra-alveolar oedema with scarce neutrophils and scanty hyaline membrane formation, it having been suggested that the virus damages the integrity of the capillary vascular endothelium rather than causing pneumonia in the more usual sense [758]. The disease should be considered in patients with unexplained respiratory failure following a febrile prodrome in the context of possible rodent contact [759]. Some hantavirus infections may respond to treatment with ribavirin [760].

### Rare and unusual bacterial pneumonias

#### *Pasteurella multocida* pneumonia

*Pasteurella multocida* is a small, aerobic, Gram-negative rod that is mainly pathogenic for animals but is an occasional cause of pneumonia in humans. The organism is distributed worldwide, being found in both wild and domestic animals including fowl. It is of economic importance as the cause of epidemic fowl cholera, haemorrhagic septicaemia of cattle and swine plague. Most recorded human infection is thought to have been acquired from domestic pets, *P. multocida* occurring as an oropharyngeal commensal in up to 55% of dogs and 70% of cats [761]. A local infection with regional adenitis may result if these animals bite or scratch humans. This may be complicated by bacteraemia with resultant metastatic sepsis in lung, bone or elsewhere. Pulmonary infection may also arise as the result of droplet spread, leading first to oropharyngeal infection and subsequently to invasion of the lungs [762,763]. *P. multocida* may colonize the lungs of patients with pre-existing lower respiratory tract infection and may cause pneumonia in such patients [764,765]. Suppuration may occur and empyema may arise as a complication (see Chapter 14).

*P. multocida* has no special growth requirements and is readily cultured from blood or sputum. It may be morphologically confused with *Acinetobacter* or other Gram-negative bacilli [766]. The treatment of choice is penicillin, which should be given parenterally as benzylpenicillin at a dose of 600 mg (0.5 megaunits) upwards, according to the severity of the infection, 6-hourly for up to 2 weeks in

bacteraemic cases or for a shorter time if the illness is less serious. The organism is usually also responsive to amoxicillin, cefuroxime and doxycycline. Erythromycin has poor activity against it.

Recovery is the rule but patients with pre-existing lung disease may be pushed into respiratory failure.

#### Group A streptococcal pneumonia

Group A streptococci, of which *Strep. pyogenes* is the most important pathogen, was one of the principal causes of death from pneumonia in the great 1918–19 influenza pandemic. *Strep. pyogenes* now rarely causes pneumonia, but when it does preceding viral upper respiratory tract infections, such as measles or varicella in children and influenza in adults, remain a common but not invariable feature. As with *Staph. aureus*, *Ps. aeruginosa* and *Klebsiella pneumoniae*, *Strep. pyogenes* is a cause of necrotizing pneumonia. The infection is spread by respiratory droplets from the nasopharynx and epidemics have previously been reported in crowded situations [767]. In contrast to this, cases of *Strep. pyogenes* pneumonia nowadays tend to occur sporadically.

The patient may be severely ill, with fever, rigors, prostration, a cough that may be productive of blood-streaked sputum, and pleuritic pain. Although patchy bronchopneumonic changes in the dependent zones of the lung are typical, the infiltrate may be more confluent and involvement of the upper lobes can occur [768]. The process is typically suppurative and may be complicated by pneumatocele formation and pneumothorax. Early pleural involvement is usual and empyemas may develop in about half of all adult cases. An associated rash similar to that seen in scarlet fever has rarely been reported [769].

Group A  $\beta$ -haemolytic streptococci may be isolated from sputum or pleural fluid and from blood in up to 15% of cases. The treatment of choice is high-dose parenteral benzylpenicillin initially. Penicillin-allergic patients may be treated with a first-generation cephalosporin (e.g. cefazolin), provided the reaction was not anaphylactic, or alternatively with vancomycin. A prolonged course of antimicrobial treatment may prove necessary, with adequate drainage of any pleural collection.

#### Meningococcal pneumonia

*Neisseria meningitidis* is a Gram-negative diplococcus much feared as a cause of fulminant bacteraemic illness and meningitis. It may occur sporadically or in epidemic form, tending to prefer younger members of the population and to cause occasional alarming outbreaks in more crowded situations, such as may be found in educational institutions and military barracks. Although not commonly appreciated, it is also a rare cause of respiratory illness, the true incidence of which is not known as the

organism is carried intermittently in the nasopharynx of up to 20% of the healthy population. Its isolation in secretions that have passed through the nasopharynx may not therefore necessarily indicate that it is the pathogen responsible for the episode of respiratory infection under investigation; furthermore it is fastidious in its growth requirements so that selective media and carbon dioxide enrichment need to be used in order to achieve optimum conditions for culture. So far over 12 different serogroups have been identified on the basis of capsular polysaccharide antigens and the majority of infections are caused by four of them.

A prospective population study, centred on Atlanta over a 5-year period, based the diagnosis of sporadic cases of meningococcal infection on positive cultures from normally sterile sites (blood or CSF). It was found that one-third of these cases occurred in patients aged 18 years or over and that just over a half of these adults had bacteraemia without any evidence of rash or meningitis. Sinusitis, purulent bronchitis or pneumonia were thought to be the cause of the bacteraemia in one-third of this group, most of whom were either over 50 years of age or in some way immunocompromised. The incidence of sporadic respiratory meningococcal infection in the presence of bacteraemia was 0.17/100 000 per year [770].

An earlier study of military recruits in which transtracheal aspiration was used to establish the diagnosis of meningococcal pneumonia found that antecedent upper respiratory tract infection was common, as were cough, sore throat, chest pain and rigors [771].

This infection has no particular clinical distinguishing features and the diagnosis of meningococcal pneumonia may be difficult to make unless infection occurs during an epidemic and unless the organism is recovered from the blood of a patient with consistent respiratory findings [772]. Recently PCR has become available for diagnosing meningococcal infection on specimens including blood and can be useful when prior antibiotic administration has suppressed culture.

The organism is likely to respond to intravenous benzylpenicillin, a third-generation cephalosporin such as cefotaxime, or chloramphenicol. It is usual to treat close contacts of patients with serious meningococcal infection with prophylactic rifampicin 600 mg 12-hourly for 2 days, although ciprofloxacin is probably as effective at eradicating carrier status [773]. A case of meningococcal bacteraemia must be notified to the public health authorities.

### **Brucellosis: *Brucella* spp. pneumonia**

Brucellosis is a chronic disease primarily affecting wild and domestic animals, being transmitted to humans by direct contact with infected live animals or their carcasses or by the ingestion of their milk. This zoonosis is caused by small Gram-negative coccobacilli belonging to the genus *Brucella*, which are found in large numbers in the milk and

urine of infected animals as well as in their products of parturition. Six species are recognized of which four are pathogenic to humans, the most common being *Brucella melitensis*, the primary reservoirs of infection for this organism being goats and sheep; the other species are *B. suis* (hares, pigs, reindeer and caribou), *B. abortus* (cattle and bison) and *B. canis* (domestic dogs). Brucellosis is a common infection in Mediterranean countries, also occurring commonly in the Arabian peninsula, Asia and Central and South America. It is uncommon in the USA, with an incidence of 1 per 200 000, most cases being reported in the southern states. It is rare in the UK where it usually occurs either as an import or as a result of laboratory or experimental mishaps, about 20 cases per year being reported [774]. Most human cases result from the ingestion of unpasteurized dairy products, such as fresh goat's milk cheese; however, the disease may also occur in occupations that entail close contact with the animal hosts in question (e.g. in abattoirs), the organism entering through cutaneous abrasions, by contact with the conjunctivae or by the inhalation of infectious aerosols.

Serological evidence of previous infection may be found in asymptomatic subjects. Those who become ill may develop non-specific symptoms, with fever (which may be undulant), sweats, malaise, fatigue and myalgia that come on either acutely or insidiously after an incubation period of between 2 weeks and 2 months. Any organ system may be involved so that the symptoms are protean. There is sometimes palpable lymphadenopathy and occasionally the liver or spleen may be felt.

Although brucellosis does not usually cause significant respiratory disease, the lungs may become involved either by the inhalation of infected aerosols, such as might arise in slaughter-houses, or perhaps more commonly by bacteraemic spread to the lungs as part of a systemic infection [775]. The patient may develop a cough that is dry [776,777]. The chest radiograph may show non-specific patchy pneumonic infiltrates, hilar and paratracheal lymphadenopathy, and miliary shadowing has also been described, so that tuberculosis is considered in the differential diagnosis [777,778]. Pleural effusions and empyemas are both rare but have been well documented [779,780].

The diagnosis depends upon a good travel and occupational history and can only be made with certainty by isolation of the organism. The organism is rarely identified in sputum but may be recovered from pleural fluid, blood or bone marrow aspirates. However, it may take up to 1 month to culture [776,779,781]. *Brucella* antibodies are most commonly detected by using a serum agglutination test, patients with active infection usually showing titres of at least 1/160. ELISAs are available, although cross-reactivity between species occurs. PCR has been applied in brucellosis but is not generally available [782].

Although tetracycline alone may be used to treat uncomplicated brucellosis, relapse rates of 5–40% have

been reported, so that it is usual to treat serious respiratory infection with two drugs. One such combination is doxycycline 100 mg orally twice daily for 6 weeks with streptomycin 1 g i.m. once daily for the first 2 weeks, which results in a relatively low relapse rate of about 6%. An alternative regimen uses doxycycline as above with oral rifampicin 600 mg once daily, both for 6 weeks, giving a relapse rate of about 14% [783,784]. Children may be treated with co-trimoxazole (5 mg/kg trimethoprim) 12-hourly orally for 6 weeks with gentamicin 2.0 mg/kg for the first 2 weeks. The majority of patients become afebrile within 10 days of starting such treatment [777].

#### **Tularaemia: *Francisella tularensis* pneumonia**

*Francisella tularensis* is a small, Gram-negative, aerobic coccobacillus that is responsible for causing tularaemia in humans. Tularaemia is a zoonosis and the main reservoir for human infection is contained among a variety of wild mammals, including rabbits, hares, squirrels, voles and other rodents, and the parasitic ticks and biting flies such as mosquitoes that parasitize them. Domestic cats may become infected and pass the organism to humans [785,786]. The organism is distributed widely in North America, particularly in the south-eastern and north central USA, approximately 200 cases per year being reported. It was first described in 1911 in Tulare County, California, hence the name. It is not endemic in South America, Africa or Australia but occurs in Asia and parts of Europe excluding the UK, although cases may be imported from endemic areas [787,788].

Infection in humans may be by contact with the carcasses of infected animals; by bites or scratches from either the animals themselves or more usually from parasitic arthropods that have fed upon their blood; by ingestion of undercooked infected meat or contaminated water; and by inhalation of infected aerosols such as may sometimes occur in laboratory workers.

The incubation period may vary from 1 day to 3 weeks. Symptomatology is protean, depending upon the route of inoculation, but malaise, fever and varying degrees of prostration are common. Cutaneous entry is commonest and may result in a skin ulcer with local lymphadenopathy (ulceroglandular form) or lymphadenopathy alone. Ocular contact may produce conjunctivitis and lymph gland enlargement, sometimes mistaken for mumps (oculoglandular form). Ingestion may produce pharyngitis, vomiting, diarrhoea and abdominal pains (oropharyngeal or typhoidal forms) [789,790]. A wide variety of rashes may also occur at some stage in one-third of cases. Pneumonia is said to occur in 7–25% of all tularaemic cases, being more common in older patients and those presenting with typhoidal symptoms and with no history of a bite [791,792]. Any of the foregoing modes of infection can produce bacteraemia and pneumonia may occur secondarily to this, primary pneumonic tularaemia being

uncommon and generally occurring following the inhalation of the organisms by microbiology laboratory workers. Patients with pneumonia usually have a dryish cough. Pleuritic pain sometimes occurs.

The pneumonic changes tend to be patchy and widespread rather than lobar and they may contain necrotizing granulomas. These granulomas may also be found on diagnostic closed-needle pleural biopsy specimens and can cause confusion with tuberculosis. Signs of consolidation are often absent and the chest radiographic appearances are as always highly variable, irregular segmental infiltrates being common [793,794]. There may be hilar lymphadenopathy and pleural effusions are sometimes evident [795].

Tularaemia will be missed unless it is considered, as the organism is fastidious and is unlikely to reveal itself when routine culture methods are used. Deliberate attempts to isolate *F. tularensis* may be rewarded by infection among the laboratory staff, and diagnosis therefore relies upon clinical acumen and either a fourfold or greater rise in serological agglutinating or ELISA titres against the organism or a single titre of 1/160 or more with a consistent clinical picture. Titres usually reach a maximum within 4–8 weeks.

The preferred treatment is a 1–2 week course of intramuscular streptomycin 0.5–1.0 g 12-hourly according to the severity of the case. Gentamicin 2–5 mg/kg daily in divided doses for 1–2 weeks is an alternative in a patient with mild to moderate disease [796–798]. Relapses may occur, although recovery is usual given appropriate treatment and it confers a high level of immunity from further episodes. Without such treatment about 15% of patients may die. A partially effective live vaccine has been used in the USA to prevent infection in occupationally exposed people.

#### **Rickettsial pneumonias**

*Rickettsia* are small, obligate, intracellular coccobacilli. *Coxiella burnetii* (the cause of Q fever) was originally known as *Rickettsia burnetii* but now has its own genus and is described earlier in this chapter. The remaining rickettsial organisms are touched on briefly here as the lungs are occasionally involved. They tend to infect small mammals (commonly rodents) and are transmitted by ticks, mites, lice or fleas according to the species. Apart from human louse-borne typhus, humans are an incidental host and not an important reservoir of infection. The infections that these rickettsiae cause are grouped clinically into the spotted fevers and typhus. The principal pathological feature in both of these groups is a vasculitic lesion caused by proliferation of the organisms in the endothelium of small vessels. The spotted fever most frequently seen in North America is Rocky Mountain spotted fever (*R. rickettsii*) and in southern Europe, Mediterranean spotted fever or boutonneuse (*R. conorii*).

The rickettsioses are characterized by fever, headache and a rash that may be petechial. The site of the insect bite is sometimes marked by an eschar or *tache noir* (black spot). A cough is common in Rocky Mountain spotted fever and pneumonic infiltrates have been described in 10–15% of cases [799]. Pleural effusions and pulmonary oedema may occur in severe cases. Pulmonary involvement has also been described in Mediterranean spotted fever, in which ARDS may also occur [800]. Similarly, pulmonary infiltrates may occur in louse-borne (epidemic) typhus (*R. prowazeki*) and in scrub typhus (*R. tsutsugamushi*) [801,802]. It is likely in all these situations that the pulmonary pathology is a consequence of lung vascular injury rather than pneumonic consolidation in the more usual sense.

Spotted fever or typhus should be considered when the illness occurs in an endemic area and in other situations when a travel or recreational history is obtained. Thus Mediterranean holiday traffic may result in imported boutonneuse fever and travel to Thailand and elsewhere in the Far East has resulted in several reports of scrub typhus pneumonia [802]. Isolation of rickettsiae can only be attempted in specialized laboratories, so that confirmation usually relies on serological testing. This is unlikely to be diagnostic before the second week of the illness so that treatment is started on the basis of clinical probability.

Most of the rickettsiae respond to treatment with tetracycline or doxycycline. Chloramphenicol may be used as an alternative in pregnancy. There have been reports of chloramphenicol- and doxycycline-resistant strains of *R. tsutsugamushi* emerging in Thailand [803].

### ***Salmonella* pneumonia**

A bronchitic cough is not uncommon in patients with enteric fever due to infection with *Salmonella typhi* or *S. paratyphi*, which are Gram-negative bacilli belonging to the family Enterobacteriaceae. *Salmonella* pneumonia is rare in adults, although more common in children in the tropics [804,805]. Patients who are ill with *Salmonella* may develop pneumonia as a result of secondary infection with another organism, although occasionally pneumonia occurs as a result of *Salmonella* bacteraemia originating from the gut or possibly the reticuloendothelial system, so that blood cultures in such cases may be positive. *Salmonella* pneumonia in adults may be more likely to occur in patients who have some degree of immunosuppression and pre-existing respiratory disease [806].

Treatment, which is initially intravenous, should be guided by sensitivities and continued for 2 weeks to reduce the chance of relapse. A fluoroquinolone such as ciprofloxacin is likely to be effective (but is better avoided in children and in pregnancy). A third-generation cephalosporin such as ceftriaxone is a suitable alternative. Strains resistant to chloramphenicol have emerged and

ampicillin is probably now about as effective as this agent. *Salmonella* pneumonia may be complicated by suppuration with lung abscess or empyema formation, in which case more prolonged therapy with drainage of any pleural collection is necessary (see Chapters 14 & 15).

### **Leptospiral pneumonia**

Leptospirosis is a zoonosis caused by motile spirochaetes belonging to the genus *Leptospira*, of which there are at least eight species. These may be subdivided into over 200 serotypes (or serovars). *Leptospira icterohaemorrhagiae* is one of the species that can cause leptospirosis in humans. The most important animal reservoir worldwide is rats but many other mammals can pass infection including cats and dogs. Leptospirosis is transmitted when water contaminated by the urine of an infected animal comes into contact with broken skin or a mucosal surface.

Infection may range from subclinical to an anicteric acute febrile illness with aseptic meningitis to a more severe illness with jaundice and a haemorrhagic tendency (Weil's disease), sometimes with renal failure and cardiovascular collapse. Most infections fall into the first category, 5–10% falling into the second. The classical illness is biphasic, with the initial bacteraemic influenza-like phase lasting up to 1 week, followed after a brief respite by the immune-mediated symptoms and signs associated with circulating antibodies that characterize Weil's disease. Pulmonary involvement in leptospiral infection is reportedly common, occurring in 20–70% of cases, but is often mild and overlooked [807]. More severe respiratory problems tend to occur in the icterohaemorrhagic form of disease. Pulmonary symptoms include cough, haemoptysis, dyspnoea and chest pain. In addition to pneumonia, leptospirosis may be complicated by massive pulmonary haemorrhage and ARDS [808,809].

The earliest radiographic abnormality appears to be bilateral small nodular opacities that may progress to produce more confluent infiltrates not confined to a single lobe. Ground-glass opacification may also occur [810]. Some of these appearances may be due to haemorrhage rather than consolidation [811].

An experienced microscopist may detect leptospirae under dark-ground illumination. Although it is possible to isolate leptospirae from blood, urine and CSF, special expertise is required and the organism is slow-growing so that laboratory confirmation of the clinical diagnosis ordinarily relies upon serology. An indirect haemagglutination test may be used for screening. A fourfold rise in the microscopic agglutination titre or a titre of 1/100 or greater is sufficient to confirm the diagnosis. Failure of a patient to seroconvert may occur if the serotype responsible for the infection is not represented in the test solution. Newer ELISAs are available and PCR has also been applied in certain centres.

Although controlled trials are lacking, there is a general view that both penicillin and tetracyclines have a beneficial effect in shortening the duration of illness and reducing the complication rate. It is currently recommended that a mild case should be treated with doxycycline 100 mg 12-hourly or amoxicillin 500 mg 8-hourly for 1 week. More severe illness may be treated initially with intravenous benzylpenicillin 1.2 g or amoxicillin 1 g 6-hourly in divided doses, continuing after clinical response with an oral agent. Third-generation cephalosporins, such as cefotaxime are probably also effective although clinical data are limited [812,813].

### Listerial pneumonia

*Listeria monocytogenes* is a Gram-positive aerobic bacillus that can infect many different types of animal and is a cause of abortions and meningoencephalitis in cattle and sheep. Human infection is mainly a food-borne infection, the organism having been transmitted from animals to humans in a variety of contaminated foodstuffs, including soft cheese, milk and meat paté.

It can cause bacteraemia and meningitis; pregnant women, their fetuses and neonates of such cases are particularly susceptible, as are other groups of immunosuppressed patients, including transplant recipients and patients with haematological malignancies; indeed *L. monocytogenes* should always be considered as one of the leading causes of meningitis in immunocompromised patients. Listeriosis occurs more frequently in patients with AIDS than in the rest of the population but remains uncommon in this group.

Pneumonia is a rare complication of infection by *L. monocytogenes* but occasional cases have been described in apparently immunocompetent patients [814,815]. Pleural effusions may also occur. The diagnosis in respiratory cases is made by culture of the organism from blood or pleural fluid.

*L. monocytogenes* appears to be equally susceptible to benzylpenicillin and ampicillin. Co-trimoxazole has been used successfully in penicillin-allergic cases.

### Melioidosis: *Pseudomonas pseudomallei* pneumonia

Melioidosis is a suppurative disease acquired in humid tropical climates. It may have many clinical manifestations, of which pneumonia is the most common. It sometimes mimics tuberculosis, so that in Western practice it needs to be borne in mind particularly in patients of Asian origin who look to have acid-fast infection of the lungs but in whom mycobacteria cannot be isolated.

*Ps. pseudomallei* is a small Gram-negative, flagellate, aerobic bacillus that grows well on standard culture media. It occurs as a natural saprophyte in soil, stagnant water and on vegetable produce in endemic areas, princi-

pally South-East Asian countries such as Vietnam, Thailand, Burma, Indonesia and Malaysia [816]. It may also occur in the tropical Northern Territory of Australia and sporadic cases have been reported in West Africa, the Near East and rarely in South America. The disease may occur in Europe and North America in subjects who have travelled from or lived in endemic areas.

Both humans and animals may become infected but rarely infect each other. It is thought that the organism gains entry when broken skin comes into contact with contaminated soil or when the organism is inhaled or ingested. Clinically apparent human melioidosis is rare, whereas evidence of subclinical infection is relatively common [817]. Serological studies in asymptomatic exposed populations have found evidence of subclinical infection in up to 9% of US military personnel serving in Vietnam [818] and in 2% of British and Australian troops engaged in the Malayan campaign [819]. Such serological evidence of infection was more common in cases of trauma, presumably as a result of wound contamination [820] and is also more common in the indigenous populations of endemic areas [821], presumably as a consequence of prolonged exposure. The impression that clinically apparent infection is rare is supported by the observation that of approximately 2.5 million US personnel serving at different times throughout the period of the Vietnam conflict only 343 cases with 36 deaths from melioidosis were recorded [820]. Intercurrent illness such as diabetes mellitus and alcoholism may predispose to clinical melioidosis [822].

### Clinical features

Clinical disease may develop within days of exposure or infection or may remain latent for many years before becoming active, a feature that may produce diagnostic difficulty for physicians living in countries in which the disease is not endemic [823,824]. The symptoms and signs are variable, being governed by the extent of the pathological process, which is essentially one of abscess formation in which suppuration produces a central area of caseation surrounded by a granulomatous margin. This process may be relatively localized to the site of cutaneous inoculation, which may be revealed by localized lymphangitis and lymphadenitis, or it may become widely disseminated in bacteraemic cases so that any organ may be involved by abscess formation and sometimes extrapulmonary suppuration may become very chronic. The lung is the organ most commonly involved.

Pneumonia may be primary, occurring as a result of inhalation, or less commonly may be secondary to bacteraemia [825]. The clinical spectrum of infection in the first case may vary from symptoms suggestive of bronchitis to suppurating pneumonia. Fever, cough, haemoptysis, pleuritic pain and weight loss may all occur. Signs of

consolidation are an inconstant finding. The chest radiograph may show a nodular or patchy upper lobe infiltrate, the areas of shadowing tending to coalesce and cavitate so that the appearances may be indistinguishable from tuberculosis; in more chronic cases the clinical picture may be entirely consistent with this disease [826].

Patients in whom pneumonia has occurred as a result of bacteraemia are much more acutely ill, often becoming prostrated and confused and frequently showing evidence of widespread disease, such as cutaneous pustules, diarrhoea, arthritis, meningitis, etc. Pneumonia that has occurred secondarily to bacteraemia may differ radiographically, with either more diffuse mottling or with larger multiple rounded opacities [826]. Pleural effusions and empyemas may occur in chronic melioidosis but are more common in the acute bacteraemic form.

### Diagnosis

A high level of clinical awareness is necessary. The diagnosis of melioidosis should be considered in any febrile illness that occurs in an endemic area and displays the foregoing clinical features, or if the patient gives a history of travel to South-East Asia or other endemic areas. Such travel need not have been recent and may have taken place many years previously. Affected patients may have an illness clinically consistent with tuberculosis but in which *Mycobacterium tuberculosis* cannot be isolated.

*Ps. pseudomallei* may be readily cultured on most media from the sputum of pneumonic cases, from pus where this is available and from blood in bacteraemic cases, although the laboratory may need to be forewarned of the possibility of melioidosis in order to avoid the misidentification and dismissal of an unfamiliar organism as a contaminant [827]. The persistent culture of a gentamicin-resistant *Pseudomonas* species may also arouse suspicion. Serological evidence of present or past infection may be provided by an antibody titre of 1/8 or greater on CFT or 1/40 on indirect haemagglutinin testing. A fourfold rise in titre provides confirmatory evidence but single high titres may persist for a long time and cannot therefore be used to distinguish between tuberculosis and chronic melioidosis [828].

### Treatment

The choice of treatment is governed by the nature and severity of infection. Asymptomatic subjects with positive serology require no treatment. Those with clinical illness require prolonged treatment with antibiotics, the choice of which should be guided by laboratory sensitivities. *Ps. pseudomallei* is usually sensitive to co-trimoxazole (trimethoprim-sulfamethoxazole), third-generation cephalosporins (e.g. ceftazidime), tetracycline and chloramphenicol. Although a Gram-negative rod, *Ps. pseudomallei*

is resistant to most aminoglycosides. Resistance to macrolides, fluoroquinolones and penicillins is also common, although the organism is usually sensitive to penicillin-clavulanate combinations such as co-amoxiclav (amoxicillin-clavulanate) and ticarcillin-clavulanate. Susceptibility may vary from country to country, so that 20% of strains from Thailand are resistant to co-trimoxazole [829]. Where a choice exists, bactericidal antibiotics should be used preferentially and in severe illness a combination of two antibiotics for the first 4 weeks of treatment is conventional. Such a combination might initially include ceftazidime (120 mg/kg daily) and co-trimoxazole (8 mg/kg daily trimethoprim), continuing with co-trimoxazole or co-amoxiclav alone as maintenance therapy for a further 3–4 months in order to prevent relapse [830,831]. In the case of persisting extrapulmonary suppuration, maintenance treatment may need to be continued for up to a year.

Without antibiotic treatment, nearly all cases who develop clinical illness die and mortality remains high at 30–50% in septicaemic cases despite treatment with appropriate antibiotics [822,832].

### Glanders: *Pseudomonas mallei* pneumonia

Pneumonia due to *Ps. mallei* occurs as a generalized infection known as glanders. This illness, now rare and largely of historical interest, is primarily an equine infection occasionally transmitted to humans. It has been eradicated in the West by a policy of slaughtering affected animals but may still occur sporadically in developing countries. Glanders is caused by a non-motile, aerobic, Gram-negative organism and is acquired either by close contact with horses, mules or donkeys or in the laboratory [833]. Infection may occur via a cutaneous abrasion, conjunctival contact, inhalation or ingestion.

After an incubation period of a few days, the patient may develop either an acute and prostrating febrile illness or a more indolent and chronic infection. Where there has been a cutaneous entry point, local lymphangitis and lymphadenitis may occur and the latter may ulcerate. Inhalation may result in nasal discharge and ulceration and suppurative pneumonia with the formation of lung abscesses. Empyema may follow. Pneumonia may also occur as a result of bacteraemia, which in turn may be associated with widespread metastatic abscesses in muscle, subcutaneous tissues and elsewhere. This suppurative process may become chronic.

The diagnosis is made by culture of sputum, blood or pus and the organism grows readily on ordinary media. A fourfold rise in complement-fixing antibody may occur over the space of 2–4 weeks. Sulfadiazine (sulphadiazine) has been used successfully in laboratory-acquired infections [833], an appropriate dose being 100 mg/kg daily for at least 3 weeks. Because of the paucity of cases, experi-

ence with modern antibiotics is lacking but treatment as for melioidosis would be a reasonable approach whilst awaiting laboratory sensitivities.

### **Bubonic and pneumonic plague: *Yersinia pestis* pneumonia**

*Yersinia pestis* is a Gram-negative bacillus that primarily produces disease in many wild rodent species (sylvatic plague), these animals constituting the natural reservoir of infection. Humans may become involved incidentally, as may dogs and cats, if bitten by a flea that has fed on a bacteraemic animal host. The incubation period is 1–7 days so that cases may travel to areas where the disease is not expected. Sporadic human cases and small epidemics are recorded in the Northern Hemisphere in the desert states of the south-western USA and on the Pacific seaboard [834]. Infection has also been recorded in parts of Africa, South America and the Far East. Great epidemics have occurred historically, such as the Black Death in Europe from the fourteenth century onwards.

#### **Clinical features**

Bubonic plague comprises fever, malaise, myalgia, prostration and painful lymphadenitis in the regional nodes drained by the flea bite. These nodes may suppurate and become painfully enlarged, forming a bubo that may be aspirated to reveal the organisms. About 10–15% of cases develop a more severe prostrating bacteraemic illness in which secondary pneumonia may be a feature [835,836]. This septicaemic plague may cause fulminant Gram-negative shock in the absence of other localizing signs. Meningitis may occur.

Primary *Y. pestis* pneumonia or pneumonic plague is caused by inhalation of the pathogen and is exceptionally rare in the Western world, most recorded cases having occurred in laboratory personnel who have handled either culture material or experimentally infected animals [837]. Veterinarians may contract the disease from cats, as did a 31-year-old man who died of pneumonic plague in Arizona in 1992 in a part of the state where chipmunks were suffering from plague [838]. Such sporadic occurrences are still occasionally put into perspective by major outbreaks of bubonic and pneumonic plague such as happened in the Indian states of Maharashtra and Gujarat in 1994 where there were over 4000 suspected or confirmed cases of plague, many of the pneumonic cases occurring in young men living in two deprived areas of Surat [839,840]. Infection in such cases may be transmitted from person to person. The signs of consolidation may at first seem slight in relation to the severity of the illness but the chest radiograph shows changes consistent with a rapidly progressive pneumonia, which may lead to overwhelming sepsis and death.

#### **Diagnosis**

Diagnosis requires an awareness of the possibility of the illness in endemic areas and should be suspected when rod-shaped, Gram-negative organisms are found in lymph node aspirates or sputum under appropriate clinical circumstances. *Y. pestis* may be demonstrated rapidly by fluorescent antibody staining. The organism grows within 48 h on simple blood media and may be cultured from aspirates of buboes, from blood or from sputum. Laboratory culture is not without risk to personnel because specimens are infectious and it should only be carried out if appropriate facilities are available to protect staff.

#### **Treatment**

Treatment is with intramuscular streptomycin 30 mg/kg daily in two divided doses for 5 days, followed by tetracycline 2–4 g daily in four divided doses to complete a 10-day course [841–843]. Gentamicin may also be used and the organism is also sensitive to chloramphenicol, which can be given intravenously in seriously ill patients, including those with meningitis. Patients should be isolated, vectors eradicated where possible and contacts advised to take prophylactic tetracycline 500 mg 6-hourly for 1 week, children aged 8 years and younger receiving streptomycin [841].

Without treatment about half of those patients with bubonic plague die and virtually all of those with pneumonic plague succumb within a few days. However, most of those who receive appropriate and prompt antibiotic treatment recover [844].

### **Anthrax: *Bacillus anthracis* pneumonia**

Anthrax is a disease mainly of herbivorous animals caused by a large, Gram-positive, spore-forming rod. The main reservoir of infection is in the soil of endemic areas such as Turkey, Iran, Sudan and Pakistan. The spores are highly resistant and may survive in such conditions for 20 years or more. When *B. anthracis* spores are ingested by a grazing animal, they cause a fatal illness so that further spores are released into the soil from the carcass, thereby allowing completion of the life cycle.

Humans are infected incidentally. This may occur in endemic areas in an agricultural setting as a result of the handling of infected animals or their carcasses. In non-endemic areas, infection may result from industrial exposure to spores that contaminate imported goat hair, wool, hides, skins or even bones used in the manufacture of bonemeal, fertilizer or glue. Suspicion surrounds a large outbreak in the former USSR, allegations having been made (and denied) that these cases resulted from an accident at a germ warfare facility that resulted in the

liberation of spores into the air in the region of Sverdlovsk in 1979, causing 42 documented cases of the inhalational form of the disease [845,846].

### **Pathology**

The underlying pathological process is not a true primary pneumonia, for once the inhaled spores reach the alveoli they are ingested by macrophages and carried to the hilar and mediastinal lymph nodes where, following a variable incubation period, they release toxins to cause a haemorrhagic mediastinitis with septic shock. Secondary dissemination and infection from this site to the lungs then results in a severe haemorrhagic pneumonia. Meningitis may also occur.

### **Clinical features**

The two principal forms of anthrax are cutaneous (95%) and inhalational (5%). Intestinal forms (due to ingestion) may occur but are not seen in developed countries. Whereas the cutaneous form produces a systemic illness associated with a painless anthrax sore (the so-called malignant pustule), inhalational anthrax or woolsorter's disease [847] results in a biphasic illness in which a seemingly mild initial fever, malaise and dry cough abruptly give way a few days later to severe dyspnoea with cyanosis.

The chest radiograph usually shows widening of the mediastinum that, in the presence of hypotension, may be mistaken for a ruptured or dissecting aortic aneurysm. In addition to this, pneumonic infiltrates and pleural effusions may also occur [848].

### **Diagnosis**

An accurate clinical diagnosis is unlikely to be reached unless the physician considers the illness in relation to occupational or other exposure to potentially infective materials. *B. anthracis* may be isolated from sputum, blood or pleural fluid, growing well on blood agar plates.

### **Treatment**

Treatment is with large doses of parenteral benzylpenicillin, up to 12 g (20 megaunits) daily, although pneumonic cases usually die within a day or two despite this. This treatment has been shown to prevent disease in exposed Rhesus monkeys, whereas cefuroxime axetil was inactive on *in vitro* testing [849].

## **Other forms of pneumonitis**

This chapter has mostly considered inflammatory lung disease caused by microbial infection. However, inflam-

mation of the lungs may also be caused physically and chemically as a result of the inhalation of a variety of irritant gases and fumes or by the effects of ionizing radiation. The inhalation of irritant gases and fumes usually occurs in an occupational setting and the clinical consequences of such exposures are described in Chapter 54. Individuals may be irradiated as a result of accidents or more often as a result of deliberate interventions by radiotherapists, in which case lung tissue may be selectively involved producing radiation pneumonitis and fibrosis. Chemical pneumonitis sometimes occurs insidiously in a non-occupational setting as a consequence of the aspiration of fatty materials, so-called lipoid pneumonia. These conditions and pulmonary reactions to bronchographic contrast media are described in the sections that follow.

### **Radiation pneumonitis and fibrosis**

Radiation-induced lung damage is most commonly seen after radiotherapy for carcinoma of the breast and also occurs when radiotherapy is directed at lung tumours, the mediastinum and the spine. There are two well-described clinical syndromes, namely radiation pneumonitis and radiation fibrosis [850,851]. Radiation pneumonitis occurs approximately 6–12 weeks and radiation fibrosis about 6–12 months after radiotherapy.

The extent to which both these syndromes develop depends upon a number of factors. These include the volume of lung irradiated and the total dose of irradiation given, including any previous courses. Radiation, formerly measured in rads, is now measured in grays (Gy). A fractionated dose of less than 30 Gy (3000 cGy or 3000 rad) is unlikely to cause clinical damage, whereas doses exceeding 40 Gy produce sequelae that are radiographically apparent [852]. Courses of radical radiotherapy may deliver a total dose of 40–60 Gy, whereas palliative treatment may rely on a single fraction of 6–8 Gy or in certain circumstances several fractions delivering a total of 20–30 Gy. The method of fractionation in radical radiotherapy is evidently important, fewer fractions for the same total dose (i.e. a higher dose rate) tending to cause more damage. The previous or simultaneous use of various cytotoxic drugs, including bleomycin and busulfan (busulphan), may also sensitize the lung to the adverse effects of radiotherapy, making radiation pneumonitis more likely [852,853]. Sometimes the subsequent administration of a cytotoxic drug may produce pneumonitis that may be strikingly limited to the anatomical field encompassed by an earlier course of radiotherapy [854]. This phenomenon may be termed 'recall radiation pneumonitis'.

### **Radiation pneumonitis**

Radiotherapy has a tendency to produce genetic damage

in any normal lung tissue that lies in its path. The sequence of events is incompletely understood but the process probably involves the production of free radicals with subsequent genetic and inflammatory cellular damage [855]. BAL samples obtained following radiotherapy have shown increased lymphocyte counts, especially in those with pneumonitis [856,857]. Radiation pneumonitis involves all components of the lung; in cases where lung subsequently becomes available for pathological study, an inflammatory infiltrate is found in the alveolar walls and interstitium, with the formation of hyaline membranes and an alveolar exudate, along with destruction of type 1 and 2 pneumocytes, endothelial injury and small vessel thrombosis [851]. The reasons that such changes are subacute, usually taking 6–12 weeks before symptoms become manifest, is unclear but has led to speculation that capillary endothelial cells are able to maintain their integrity until chromosomal aberrations prevent further replication, at which point the leakage of proteinaceous fluid across their walls occurs [858]. The development of symptoms at a stage earlier than 6 weeks implies that a more severe episode of pneumonitis will develop. The risk of radiation pneumonitis increases with the dose and the proportion of lung irradiated, so that the radiotherapist is always concerned to limit the field of irradiation.

### *Clinical features*

Symptoms of radiation pneumonitis are estimated to occur in approximately 5–15% of patients who receive radiotherapy to the chest [851]. The clinical features of radiation pneumonitis include the onset of dyspnoea, usually accompanied by a cough that may be dry or productive of pinkish sputum. A fever and associated constitutional symptoms may develop. Chest pain is sometimes present as a result of associated pleurisy or as a consequence of rib fractures that may themselves be caused by radiation necrosis of bone. Auscultatory signs tend to be sparse, a few crackles being sometimes heard over the affected area of lung. A pleural effusion may develop but this is an unusual accompaniment. Rarely, severe dyspnoea of sudden onset may develop, being accompanied by cyanosis and respiratory failure, the clinical picture resembling ARDS [859,860].

The chest radiograph shows poorly defined, hazy, reticulonodular opacification characteristically confined to the field of irradiation, so that the abnormal area of shadowing often has a sharp, straight edge, the pneumonitis being abruptly limited in its extent by the margin of the radiotherapy port. This has been referred to as the 'straight edge effect' and may produce a quite striking appearance on the film. Unsurprisingly, high-resolution CT is more sensitive than plain radiography at detecting changes in radiation pneumonitis [861]. This form of imaging may also be helpful in separating radiation

damage from other differential diagnoses, such as lymphangitis carcinomatosa.

Occasionally a phenomenon known as 'recall pneumonitis' may be observed, in which pneumonitis may occur in association with cytotoxic therapy within the distribution of a previous radiotherapy field as indicated by a straight edge effect; it has been hypothesized that the radiotherapy sensitizes or primes the lung tissue to the toxic effect of the chemotherapeutic agent [862].

### *Treatment*

Mild radiation pneumonitis requires only reassurance and supportive therapy. When symptoms are more severe, 60 mg of prednisolone daily may be given until the pneumonitis begins to remit, after which the dose is reduced, according to response, to approximately 20 mg daily, from which point medication may be tapered off over the space of several weeks. Such treatment is empirical as there have been no controlled trials to assess its efficacy in humans. However, animal studies suggest that benefit may be expected [863]. Furthermore, it has been noticed that the withdrawal of therapy from patients already taking corticosteroids at the time of radiotherapy may coincide with the onset of radiation pneumonitis, which clears once the drug is restarted [851,864]. However, routine prophylactic corticosteroid administration is not justifiable.

Anticoagulants have been used in the past in an attempt to prevent radiation-induced lung damage, the rationale being the limitation of vascular occlusion in affected lung tissue, although no convincing benefit has been shown [865].

The outcome in radiation pneumonitis is usually one of spontaneous improvement within a week in mild cases, others recovering more slowly following treatment with corticosteroids as above. The most severe cases deteriorate progressively and die [865].

### **Radiation fibrosis**

Radiation fibrosis develops 6–12 months or more after attempts at radical radiotherapy as a result of the genetic damage sustained by lung tissue, which ultimately results in scarring with disruption of normal lung architecture. To some extent this may be a continuum of the subacute process described but need not have been preceded by the more acute symptomatic radiation pneumonitis described above.

### *Clinical features*

When radiation fibrosis is extensive enough to cause symptoms, patients usually exhibit varying degrees of dyspnoea. Occasionally this may be disabling, being accompanied by a severe restrictive impairment of lung

function and by respiratory failure that may lead to cor pulmonale [866]. The chest radiograph shows localized fibrotic shadowing in the field of irradiation. Patients in whom serial radiographs have been taken from the stage of radiation pneumonitis sometimes show a gradual evolution of change [867] that may culminate in the usual features of fibrotic loss of lung volume, with distortion of surrounding structures. These features are reflected by the pathological findings of dense fibrosis with collagen formation in those cases that come to postmortem examination [851].

In practical terms it may be difficult to distinguish between radiation-induced lung disease and recurrent neoplastic disease or infection. The presence of changes that extend beyond the radiotherapy field implies another cause and the availability of serial chest radiography or CT sometimes makes the distinction clearer. Unsurprisingly, there is no evidence of any benefit accruing from the use of corticosteroids to treat late radiation fibrosis.

### **Lipoid pneumonia**

Lipoid pneumonia develops as a result of the aspiration of fatty or oily material into the lungs. It is an infrequent cause of morbidity that is likely to evade diagnosis unless considered in cases of apparently unresolving pneumonia.

#### **Causes**

The aspiration of any oil, whether animal (e.g. cod-liver oil), vegetable (e.g. olive oil) or mineral (e.g. paraffin), may result in lipoid pneumonia. Liquid paraffin has been responsible for most cases as a consequence of its relatively common usage for aperient purposes over prolonged periods of time [868]. Other causes have included the habitual use of mineral oil-based nasal drops [869]; the application of liquid paraffin eye drops for xerophthalmia, this topical preparation presumably finding its way to the lungs via the nasolacrimal ducts and nasopharynx [870]; the aspiration of milk feeds or cod-liver oil in children with feeding difficulties [871]; the aspiration of *ghee* (rendered animal fat) following the cultural practice of force-feeding infants with this substance in south-western Saudi Arabia [872]; the aspiration of oil-containing folk remedies [873]; the aspiration of diesel oil by ship-wrecked sailors [874]; the inhalation, in Guyana, of the smoke of 'blackfat' tobacco, to which oil has been added in the production process [875]; the inhalation of fine mists of mineral oil used in industry for coolant or lubricating purposes or of hot oils inhaled by those working in close proximity to burning fat [876,877].

Sometimes the possible cause is overlooked until histology suggests the diagnosis, as in the case of a woman who

habitually applied Vaseline petroleum jelly to her nostrils before retiring to bed [878], or the patient who ingested oil-based cutaneous emollients for laxative purposes [879], or the woman who misused a pressurized spray lubricant (WD-40) to relieve her rheumatism [880]. Even more bizarre cases of lipoid pneumonia sometimes arise, for example due to the inhalation of paraffin-based ignition fluid by a clown in the course of her fire-eating act [881], or the case of a psychologically disturbed patient who accidentally self-administered olive oil intravenously while attempting to inject this substance into his scrotum [882].

#### **Age of the patient**

Lipoid pneumonia is usually encountered in elderly patients as they are the most likely group to have made habitual use of liquid paraffin. However, it may occur at any age and was first described in children with feeding difficulties that resulted in the aspiration of milk or cod-liver oil [871]. A disturbed swallowing mechanism in any patient may act as a predisposing factor but is not a prerequisite, as it has been shown that iodinated oil placed in the nostrils of healthy sleeping subjects can be detected radiographically in their lungs the next morning [883].

#### **Pathology**

Vegetable oil is emulsified and mainly removed by expectoration, causing little damage to the lung. Animal fat is hydrolysed by lung lipases, resulting in the formation of fatty acids that may produce a severe inflammatory reaction, with haemorrhagic bronchopneumonia [474,884]. Mineral oils such as paraffin are not hydrolysed but are emulsified and in part removed by coughing. Some of the residuum is transported to regional lymph nodes, whilst that fraction remaining in the lungs acts as a foreign body, being ingested by macrophages which eventually disintegrate, releasing the oil once again. Examination of lung tissue may show large amounts of foamy vacuolated material in the alveoli, both lying free and as oil droplets within alveolar macrophages [885,886]. This results in alveolitic changes and the persistence of oil in the lungs for a sufficient length of time produces fibrosis, which may at length be complicated by secondary infection. Sometimes a chronic localized granulomatous and fibrotic process may become set up, so-called paraffin granulomas or paraffinomas, which clinicians may mistake for neoplasms [887].

#### **Clinical features**

There may be few symptoms and signs; thus when a liquid paraffin aperient or nose drops are responsible, the patient is unaware of a causal relationship, as mineral oil is so

bland that it may pass the glottis and enter the lungs without even evoking a cough. Symptoms may remain minimal despite the development of radiographic signs, although cough, sputum production, haemoptysis and dyspnoea may occur and crackles may be present over affected areas of lung.

There are no specific radiographic findings but the lower zones are more commonly affected, presumably as a result of the gravitation of oil to these most dependent parts. The right lower lobe is affected more often than the left but opacification is frequently bilateral. The infiltrates may mimic patchy pneumonic consolidation, which sometimes cavitates; at other times reticulonodular appearances are produced [888–890]. More localized irregular mass-like lesions may be paraffinomas, their true nature becoming evident only after resective surgery for supposed lung cancer. CT may demonstrate areas of low attenuation consistent with fat [891].

### Diagnosis and treatment

The diagnosis should be reached by obtaining a history of mineral or other oil usage in patients with chest radiographic appearances consistent with chronic or unresolving pneumonia. Once the diagnosis is considered, the cytological examination of sputum or BAL material may show large macrophages with strongly positive intracytoplasmic staining for lipid, if special stains such as Oil-red O are used [886,892,893]. However, caution should be exercised as less strong lipid-staining reactions may be produced by the endogenous release of lipids when lung tissue breaks down distal to an obstructed airway [893,894]. Characteristic histological and lipid-staining

changes have been demonstrated on transbronchial lung biopsy material [878,890] but sometimes the diagnosis is only made after more invasive surgical procedures, as alluded to above.

Treatment is by removal of the cause. Prednisolone has been used but there are no controlled trials, experience being limited to case reports with variable results [895,896]. There have been occasional reports of the successful use of whole lung lavage [897]. Prevention may be partly achieved by the avoidance of laxatives and nose drops containing mineral oil.

### Pulmonary reactions to bronchographic contrast media

Abnormal pulmonary reactions have been described following the use of radiographic contrast media employed in bronchography. These have occurred up to 5 days after examination when oily propyl iodone (Dionosil) has been used. Clinical features have included fever, productive cough and breathlessness. Crepitations may be heard over both lung fields and the chest radiograph may show bilateral patchy shadowing. An apparent response was obtained in three cases following treatment with 20–60 mg of prednisolone daily [898].

Other oily contrast media such as Lipiodol (40% iodine in poppy seed oil) may cause the formation of granulomatous lesions if normal clearance from the lung is not achieved [888]. These reactions are probably of largely historical interest as the commercial production of bronchographic contrast media has ceased following the adoption of CT as the investigation of choice in cases of suspected bronchiectasis.

# EMPHYEMA

DOUGLAS SEATON

The word 'empyema' is used to denote the presence of pus in a natural body cavity. In respiratory medicine that space is the pleural cavity and the term is often also used to cover pus in a postpneumectomy space. Some texts still use the Latin term for thoracic empyema, *empyema thoracis*, but are seldom consistent enough to embrace the classical plural form.

The diagnosis can only be confirmed by examination of pleural fluid. If this is frankly purulent, then no doubt remains; if it is not obviously turbid, then diagnostic confirmation requires the microscopic finding of a cell count showing a predominance of neutrophil leucocytes. The finding of organisms on Gram stain or culture is also confirmatory, although these may have been suppressed by antibiotics and are not always detectable. Empyemas are sometimes described as acute or chronic but the division between the two is indistinct and arbitrary, the latter term usually being reserved for those cases that have passed through the early exudative stage to reach a stage of organization in which a pleural rind has formed (see below).

Early descriptions of empyema and its treatment by surgical drainage have been attributed to Hippocrates [1]. By the nineteenth century, pleural aspiration, underwater seal drainage and rib resection were all practised, but despite these best available forms of treatment the condition was frequently fatal [2]. So it was with Sir William Osler in 1919 [3]. Others fortunate enough to recover, including notables such as King George V, often had to endure a protracted illness [4]. Nowadays with the availability of antibiotics, the more affluent parts of the world enjoy relative freedom from suppurative lung disease so that the finding of an empyema may come as something of a surprise. This is not the case in most parts of the globe where thoracic empyema continues to present a considerable problem.

## Pathology

Once infected by pathogenic organisms, the connective

tissue layers within the pleural membranes become oedematous and produce an exudation of proteinaceous fluid that starts to fill the pleural cavity. The deepest layers of the pleural membrane are relatively impervious so that infection tends to be contained within the pleural cavity itself and spread beyond it is unusual. At this early *exudative* stage the pleural fluid is thin with a relatively low white cell count and the visceral pleura and underlying lung remain mobile [5]. If the infection proceeds unchecked by antimicrobial agents, the inflammatory process continues so that newly formed layers of fibrin become laid down on the epithelial surface within the pleural cavity, particularly on the parietal pleura. The empyema fluid now becomes thicker and more turbid, containing a higher white cell count. With the deposition of fibrin on both pleural surfaces, lung movement in this later *fibrinopurulent* stage may become increasingly restricted [5]. Depending upon the nature of the infecting organism and whether or not antibiotics and drainage procedures have been employed, these thickened fibrinous layers organize as collagen and become vascularized by an ingrowth of capillaries. This *organizational* stage may begin within 2 weeks [6] but usually takes 4–6 weeks to develop to a point at which the empyema cavity becomes surrounded by a cortex, 'peel' or 'rind' that may be more than 2cm thick [7]. By this time the empyema contains frank pus, which may be viscid. The inner layers of the thickened empyema cortex continue to show a considerable inflammatory cell infiltrate and the fibrous outermost layers exert an increasingly restrictive effect, both compressing the underlying lung (the so-called 'trapped lung' effect) and also tending to draw the overlying ribs together, ultimately producing a chest deformity with a dorsal scoliosis that is concave towards the affected side.

An empyema may become localized to one part of the pleural cavity or it may involve the whole of it. Such large empyemas may become loculated into smaller collections by the development of septate fibrinous bands, making the work of percutaneous aspiration difficult or impossi-

ble. Ultimately an inadequately treated empyema cavity may become obliterated and its rind may calcify, producing a so-called fibrothorax, particularly in the case of old tuberculous pleural infection (Fig. 14.1).

## Pathogenesis

### Introduction of infection

Empyemas may be of traumatic or non-traumatic origin (Fig. 14.2). Non-traumatic cases are more commonly encountered in peaceful society and usually arise as the result of direct extension from an adjacent site, lung infection being the most common cause, accounting for over half the cases [8,9]. Aspiration pneumonia forms an important subgroup and a significant number of these patients are alcoholics [10]. Obstruction of a bronchus as a result of lung cancer or an inhaled foreign body occasionally underlies the pneumonic process. Suppurative lung disease, such as bronchiectasis (see Chapter 28) or lung abscess (see Chapter 15), are less commonly associated than pneumonia. Patients with rheumatoid disease are peculiarly susceptible [11]. Surgical trauma ranks as the second most frequent cause after pulmonary infection, this group including instrumentation and rupture of the oesophagus, leakage of an oesophageal anastomosis after resection and the development of a bronchopleural fistula following pneumonectomy. Organisms may also be introduced by pleural aspiration of any effusion or by tube drainage of a malignant effusion. Infection is the commonest present-day complication of that dwindling group of

patients who were treated for pulmonary tuberculosis by surgical plombage in the era before antibiotics [12]. Less common sources of infection include abdominal sepsis, which may first localize to form a subphrenic abscess before extending to the pleural cavity by lymphatic drainage [10]. Liver abscesses, including those caused by *Entamoeba histolytica*, may also be implicated (see Chapter 22) and sepsis in the pharynx, thoracic spine or chest wall may extend to the pleura, either directly or via the tissue planes of the mediastinum [13].

Non-surgical penetrating trauma to the chest may occur as a result of gunshot wounds, blast injuries and stab wounds. From the time of the First World War to the Korean War, such injuries were associated with empyema in about 25% of cases [14]. By the time of the Vietnam conflict the figure had fallen to around 6%, presumably as a result of prompt surgical drainage of haemothorax and the use of antibiotics [15,16]. The chance of such injuries resulting in empyema has been found to be doubled if a haemopneumothorax as opposed to a haemothorax is present [17].

### Microbiology

The pathogenic organisms isolated in cases of empyema vary according to whether (i) antibiotics have been used, (ii) the infection has arisen as a complication of community-acquired or aspiration pneumonia or as a result of some other predisposing factor such as oesophageal surgery, and (iii) the patient is an adult or a child. In general, anaerobes and Enterobacteriaceae are often present in mixed cultures, whereas other organisms

**Fig. 14.1** Right-sided empyema with air–fluid level due to bronchopleural fistula that developed during an aeroplane flight. Note calcified wall medially, raising suspicions of a tuberculous aetiology.

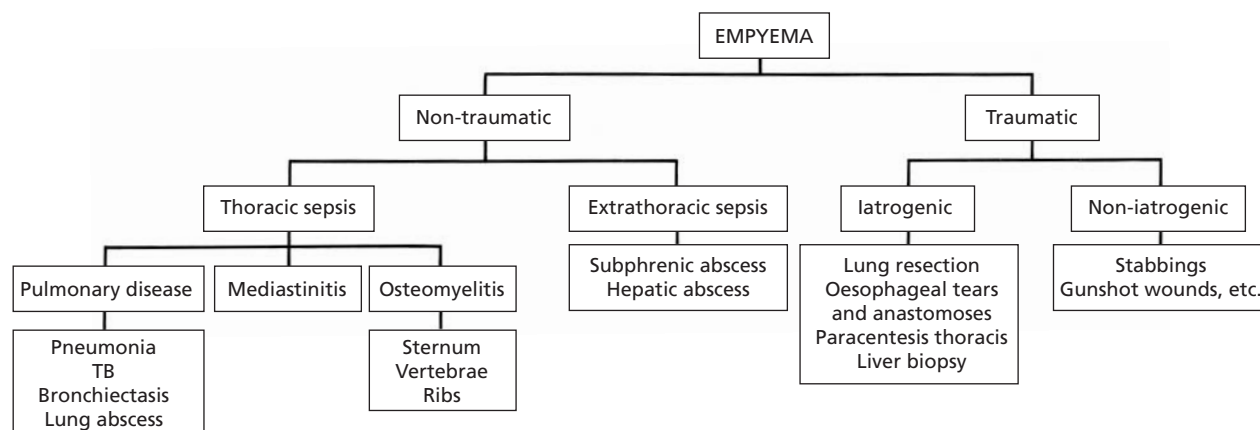

Fig. 14.2 Pathogenesis of thoracic empyema.

such as *Streptococcus pneumoniae*, *Staphylococcus aureus* and organisms of the *Strep. milleri* group (syn. *Strep. intermedius* group) may be recovered as pure isolates [11].

#### Influence of antibiotics

Before antibiotics were available, pneumococci (*Strep. pneumoniae*) and  $\beta$ -haemolytic streptococci (e.g. *Strep. pyogenes*) caused empyemas with much greater frequency than is now the case [18]. Thus in a study of 3000 cases of non-tuberculous empyema, published from data collected before the Second World War, pneumococci were responsible for 64%,  $\beta$ -haemolytic streptococci for 9% and *Staph. aureus* for 7% of the remainder [19]. The decline of empyema as a complication of pneumococcal pneumonia has resulted in an alteration in the frequency with which the major pathogenic bacteria are found in empyema fluid, so that when all aetiologies are considered Gram-negative bacilli such as *Escherichia coli*, *Pseudomonas aeruginosa*, *Proteus* species and *Klebsiella pneumoniae* made up the largest group and accounted for almost 30% of positive isolates in one series [8]. *Staph. aureus* accounted for slightly fewer isolates (25%), whereas the proportions of pneumococci and anaerobic organisms were 15% and 11% respectively. However, the pneumococcus remains a very important pathogen in groups of young previously healthy adults, as evidenced by a report of 197 cases of empyema from two large military hospitals in which *Strep. pneumoniae* accounted for 70 isolates [9]. The author has seen several cases of pneumococcal empyema developing in patients who had been inappropriately treated with the quinolone antimicrobial ciprofloxacin as an oral first-line agent for community-acquired pneumonia. Viridans organisms of the *Strep. milleri* group (now referred to as *Strep. intermedius* group) have also been identified as an

important pathogen in empyema and lung abscess [20–23]. Anaerobic infections (usually bacteroides, peptostreptococci and fusobacteria) are probably more common than is often reported, the frequency with which they are found to some extent reflecting the care, or lack of it, that is taken in looking for them [24,25]. Mixed bacterial infections commonly occur, one detailed microbiological study recording both anaerobic and aerobic organisms in 54% of cases and aerobes in only 38%, whereas anaerobic organisms were the sole isolate in only 8% of cases [20]. It is clear that anaerobic cultures should be carried out routinely whenever pus is obtained from the thoracic cavity, but care should be taken with the specimens and liaison with the microbiologist or infectious disease specialist should be close [25,26]. Despite the fact that the majority of patients have already received an antibiotic by the time empyemas are diagnosed, it is nevertheless usual for organisms to be isolated, the pus being found to be sterile in only one-third of cases [8]. A recent British multicentre study of empyema found that anaerobes and Enterobacteriaceae were often present in mixed culture, whereas pneumococci, staphylococci and *Strep. milleri* organisms were usually pure isolates [11]. In this series, *Strep. milleri* organisms and anaerobes were each identified in about one-third of patients, the pneumococcus in about one-quarter and *Staph. aureus* and Gram-negative aerobes each in about one-sixth [11].

#### Influence of predisposing factors

Empyemas arising in adults as a complication of community-acquired pneumonia are often pneumococcal, whereas those occurring as a consequence of frank aspiration are more likely to contain anaerobes and, as with lung abscess (see Table 15.1), often occur in association with alcoholism, epilepsy or other cause of a depressed conscious level, in which situations there may be palatal weakness or incoordination, particularly if there is coexisting dental or other oropharyngeal sepsis. Aerobic

Gram-negative enteric bacilli are likely to be implicated in the spread of infection to the pleura from below the diaphragm or as a result of oesophageal instrumentation [8]. In addition to aerobic Gram-negative bacilli, there is also a high frequency of *Staph. aureus* infection in empyemas following external trauma and in those that complicate haemothorax [27,28]. This organism may also be found more commonly in pleural fluid cultures of patients with human immunodeficiency virus (HIV) infection compared with immunocompetent patients [29]. Uncommon microbial causes (see below) such as mycobacteria or fungi may be causal in immunosuppressed patients, such as those with organ transplants or AIDS, although an empyema is rarely found in isolation in these patients who often have disseminated infection. Acid-fast bacilli are demonstrated on pleural fluid microscopy in about 15% of AIDS patients with tuberculous pleural effusions compared with about 1% of tuberculous pleural effusions in the non-AIDS population, a finding in keeping with the supposition that such effusions in the immunocompetent population are usually caused by delayed hypersensitivity reactions to the mycobacterium rather than by direct infection of the pleural space by the organism [29].

### Influence of age

*Staph. aureus* is a common infecting organism in childhood empyema, particularly in infancy, accounting for 92% of empyemas in children under the age of 2 years in one early series [30,31]. Gram-negative organisms other than *Haemophilus influenzae* are relatively unusual causes of empyema in childhood, although *Ps. aeruginosa* was second in frequency to *Staph. aureus*, being isolated in 10 of 57 Nigerian children in one series [32]. *H. influenzae* is an important pathogen in children, accounting for 24% of isolates in one retrospective study compared with 30% for *Strep. pneumoniae* and 38% for *Staph. aureus* [31]. Anaerobic and mixed infections are also important in children, aerobes accounting for 67% of infections, anaerobes for 24% and mixed infections for 10% in the report by Brook [33]. Of the aerobes, *Staph. aureus* accounted for 17% of isolates, whereas the proportions for the pneumococcus and *H. influenzae* were 22 and 25% respectively [33].

### Uncommon microbial causes

Empyema may be caused by many groups of organisms other than the more common ones referred to above. Tuberculous empyema, now uncommon in 'developed' countries, should never be forgotten and may be particularly indolent [34,35]; this and other complications of tuberculosis are discussed in Chapter 17. Empyema may be rarely caused by fungi, particularly in immunocompromised hosts. *Aspergillus* species may infect the pleural space and result in empyema formation; before the antibi-

otic era, this sometimes occurred as a late complication of cases of pulmonary tuberculosis where artificial pneumothorax or thoracoplasty had been employed [36]. *Cryptococcus neoformans* has little virulence other than for immunocompromised hosts in whom infection may cause serious pulmonary and more rarely pleural disease [37,38]. *Blastomyces dermatitidis* may cause chest wall as well as pulmonary disease, and infection may arise without predisposing factors [39]. Blastomycosis is not endemic in Europe, but in the USA is found particularly in the river basins of the Ohio, Missouri and Mississippi and to the west of Lake Michigan. Another fungus *Coccidioides immitis* causes coccidioidomycosis. This may produce an acute self-limiting febrile illness known as San Joaquin Valley fever, a chronic cavitary and suppurative pulmonary disease of which empyema is an occasional and well-described complication [40,41]. The disease is endemic in the south-western states of the USA and in parts of Central and South America but is occasionally seen in Europe as a result of modern forms of travel. Empyema is a rare complication of histoplasmosis [42].

*Actinomyces* is a genus of common anaerobic Gram-positive filamentous bacteria that live commensally in the mouth and rarely cause chronic, granulomatous, suppurative infection of the lung and pleural space, classically resulting in extensive sinus formation with so-called 'sulphur granule' discharge. Such manifestations of actinomycosis are now rare, as infection is usually contained by treatment with antibiotics [43–46]. *Nocardia* is a related genus of weakly Gram-positive but aerobic filamentous bacteria that was erroneously thought to be mycotic. Resultant pulmonary nocardiosis may produce similar suppurative pleural and chest wall involvement to that seen in actinomycosis but such infection is rare in immunocompetent hosts [47,48].

Clostridia are anaerobic organisms found as normal faecal flora and may colonize the skin by contamination. They rarely cause pleuropulmonary infection in the absence of some form of penetrating chest wall trauma, which is often iatrogenic, but can sometimes also reach the pleura as a result of aspiration of oropharyngeal contents or secondary to bacteraemia [49]. These Gram-positive bacilli (usually *Clostridium perfringens*) have been well described as causative agents of both necrotizing pneumonia and empyema [49–52].

Organisms belonging to the aerobic Gram-positive genus *Bacillus* are infrequent pathogens but may rarely cause necrotizing pneumonia and empyema in patients who are immunosuppressed, in which situation *Bacillus cereus* is most frequently implicated [53–55]. Group A streptococci, of which *Strep. pyogenes* is the most important pathogen, was an important cause of suppurating pneumonia and empyema in the pre-antibiotic era (see Chapter 13) but is now a rare cause of sporadic cases. *Brucella*

*melitensis* may rarely cause empyema, and brucellosis should be considered in patients who have stayed in endemic areas such as the Middle East, the Mediterranean, Latin America and Asia [56]. *Pasteurella multocida*, an aerobic Gram-negative coccobacillus found commonly in the oropharynx of domestic and wild animals, may cause pneumonia and empyema in patients with chronic pulmonary disease [57–59]. *Salmonella enteritidis*, of which there are over 1700 serotypes, may unusually cause pneumonia and rarely results in empyema, sometimes in the absence of gastrointestinal tract symptoms [60–63].

Hydatid disease, caused by cestodes of *Echinococcus* spp., may involve the pleural space, as may paragonimiasis, a disease caused by the lung fluke, *Paragonimus westermani*, a trematode endemic in the Far East and parts of Africa [64–66]. An empyema associated with systemic and pleural fluid eosinophilia is highly suggestive of such infection [67].

Protozoa belonging to the genus *Trichomonas* have been recorded in empyemas but are an exceptionally rare cause of this condition [68,69]. Amoebiasis is the third leading parasitic cause of death in the world. Pleural complications include right-sided sympathetic effusions, although *Entamoeba histolytica* infection may also cause empyema, usually when an amoebic abscess within the right lobe of the liver ruptures and erodes through the diaphragm to involve the pleural cavity directly [70,71].

Lung colonization in cystic fibrosis by the relatively drug-resistant *Burkholderi cepacia* (previously known as *Pseudomonas cepacia*) is well described and this organism may cause pleural infection in such patients when they are immunocompromised following lung transplantation [72–74]. *Listeria monocytogenes* has been described as a rare cause of empyema in an HIV-infected patient [75].

## Clinical manifestations

The clinical manifestations of an empyema vary widely depending on both the nature of the infecting organism and the competence of the patient's immune system. The spectrum ranges from an almost complete absence of symptoms to a severe illness with all the usual manifestations of systemic toxicity. The presenting features may vary according to the way in which the empyema has arisen: following pneumonia (see Chapter 13), surgery or other forms of trauma or as a consequence of mediastinitis (see Chapter 49) or subdiaphragmatic sepsis.

The onset of symptoms may be more indolent in cases of anaerobic infection. The presenting features are often non-specific and may not suggest respiratory disease to the primary care physician, so that the diagnosis may be delayed if a chest radiograph is not requested [11]. Fever is common, although if the empyema cavity is well walled off or the patient elderly this need not be present. General malaise and loss of weight are common features as is pleu-

ritic pain, which may take the form of dull chest wall discomfort. Dyspnoea may result from the compression of underlying lung by the empyema or from primary disease involving the lung itself. A cough is frequent and in the presence of a bronchopleural fistula variable quantities of purulent sputum, which is sometimes foul-smelling, may be expectorated. The volume of sputum may depend on the position that the patient adopts or, in the case of air travel, the pressure of the aeroplane cabin [34].

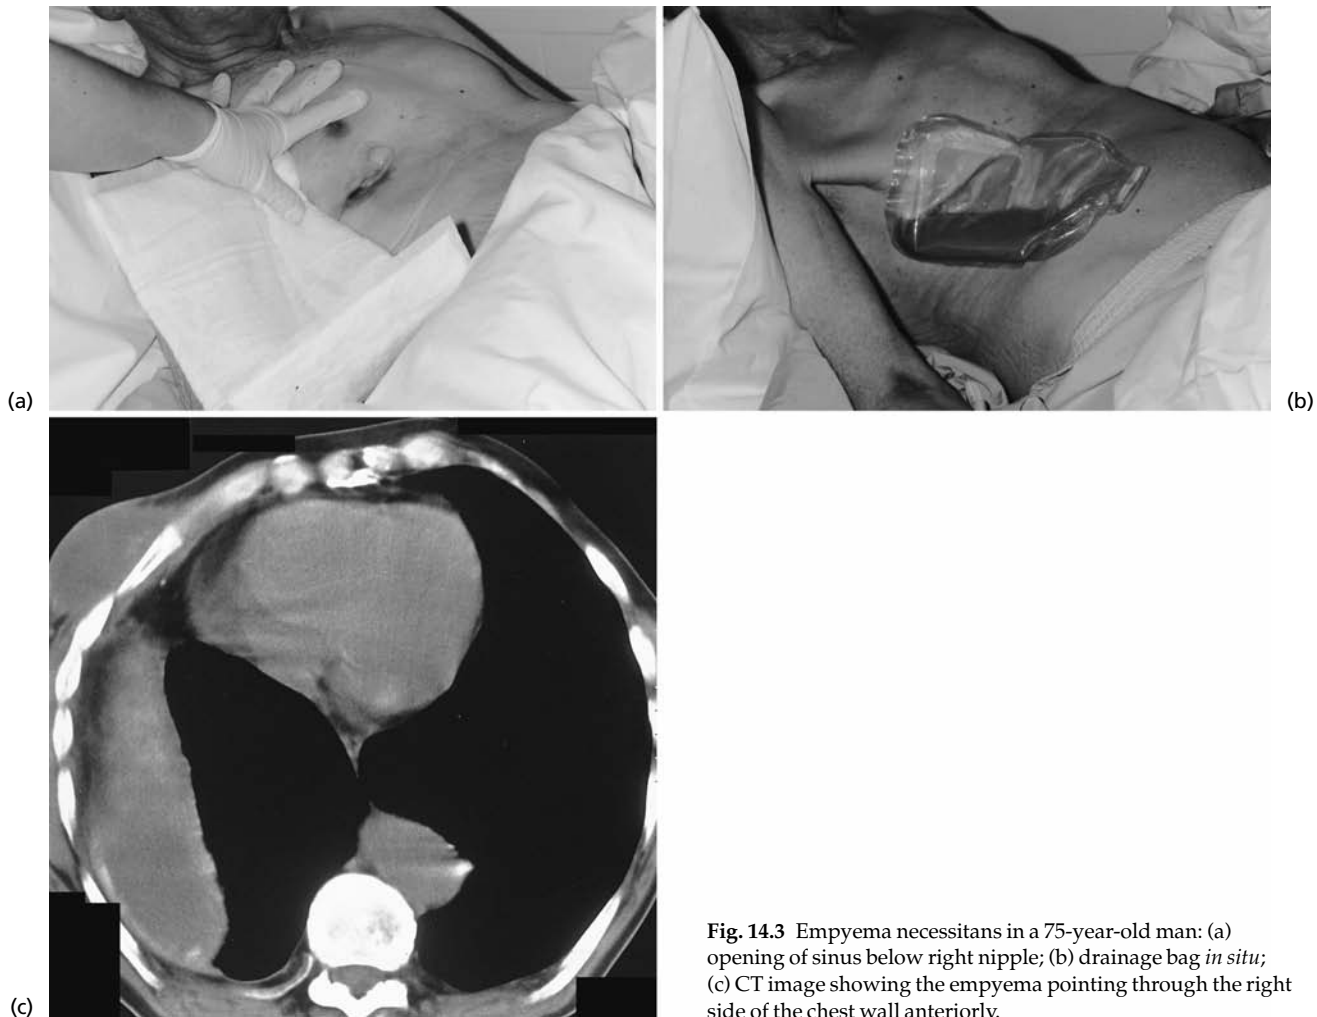

In addition to the signs of any associated disease, the physical signs of an empyema are those of a pleural effusion (see Chapters 6 & 43). Finger clubbing may be an accompaniment of more chronic empyemas. The suppurative process, if undrained and uncontrolled by antibiotics, may extend beyond the pleural cavity, with pointing occurring in an intercostal space often close to the sternum where the chest wall is thinnest. The term 'empyema necessitatis/necessitans' may be used to denote any such lesion that has ruptured through the chest wall to the subcutaneous tissues, ultimately reaching the surface through the skin to form a discharging sinus (Fig. 14.3). Occasionally suppuration may track caudally behind the diaphragm, tending to point and discharge in either the lumbar region or the groin. Such behaviour is unusual in modern practice but may occasionally be seen with tuberculous, actinomycotic and other empyemas [46,73]. The finding of a mouth full of decaying teeth may increase the chance of the responsible organisms being anaerobic.

## Diagnosis

The possibility of a complicating empyema should always be borne in mind in a patient with a lower respiratory tract infection. Although the history and physical findings may be suggestive, the diagnosis can only be made with confidence when suspicious chest radiographic findings lead to thoracentesis. Other findings, such as a mild normochromic normocytic anaemia, neutrophil leucocytosis and hypoalbuminaemia, are commonplace and non-specific but should alert the clinician to the possibility of empyema in a patient with an abnormal chest radiograph.

## Diagnostic imaging

The chest radiographic appearances of empyema may, in the early stages, be identical to those of an uncomplicated pleural effusion. As time passes, fibrosis develops around the empyema cavity so that the fluid is contained in one location, irrespective of the patient's posture. This homogeneous shadowing usually extends upwards from either hemidiaphragm and a useful clue is the common finding of posterolateral loculation, producing a typical appearance on the lateral chest film, with an opacity that is convex anteriorly, sometimes tapering at its upper and lower ends and extending into the thorax from the direc-

**Fig. 14.3** Empyema necessitans in a 75-year-old man: (a) opening of sinus below right nipple; (b) drainage bag *in situ*; (c) CT image showing the empyema pointing through the right side of the chest wall anteriorly.

tion of the spine (Fig. 14.4). This so-called 'D-shaped shadow' may be associated with obliteration of the ipsilateral costophrenic angle on the posteroanterior (PA) view. The appearances on the PA view not uncommonly mislead and the lateral projection helps to reduce doubt. An air–fluid level may be present, indicating an associated pneumothorax, bronchopleural fistula, the presence of gas-forming organisms such as clostridia, or a previous imperfect thoracentesis that has allowed air into the chest (see Fig. 14.1). Interpretation of the radiograph may be complicated by underlying pulmonary shadowing and the differential diagnosis may include delayed resolution of pneumonia, lung abscess, tumours of the lung, mediastinum and pleura, hydatid cyst and partial lung collapse. When unequivocal radiographic evidence of fluid is not present, thoracentesis may be carried out with some uncertainty as to the likely result. This uncertainty may be reduced by the use of diagnostic ultrasound which, provided the empyema abuts the chest wall, is capable of detecting a localized pocket of fluid that shows as an echo-

transmitting (anechoic or echo-free) space bounded by the wall of the cavity [76]. Ultrasonography may also show septa when there is loculation, and a more echogenic image is obtained as organization takes place. Ultrasound is also very useful in targeting an empyema for needle or tube drainage, particularly when access proves difficult, and it is probable that its use reduces delay in diagnosis. CT of the thorax may be similarly helpful, often showing a rind of pleural thickening, frequently with a typical encapsulated biconvex configuration, and sometimes also unexpected collections [77,78] (Figs 14.5 & 14.6). Associated intrathoracic inflammatory lymphadenopathy on CT is a common finding [79]. Radionuclide scanning, in which leucocytes or non-specific IgG are tagged with radioactive indium [ $^{111}\text{In}$ ], has also been used to localize collections of pus in various body cavities, although the utility of this investigation is limited by both the spatial resolution of the gamma camera and the fact that false-positive results may be produced by other unrelated intrapulmonary pathology; thus it appears to have no advantage over

(a)

(b)

**Fig. 14.4** Posteroanterior (a) and lateral (b) views of large right loculated empyema.

conventional radiography supplemented by ultrasound and/or CT examination [80,81].

### Microbiology

Provided that grossly purulent fluid is obtained at thoracentesis the diagnosis is confirmed. The specimen should

be taken to the laboratory with minimum delay and anaerobic as well as aerobic cultures should be set up as a matter of course. In addition to routine Gram staining, liaison with the laboratory is important so that a specific search for acid-fast bacilli and fungi is made in appropriate cases. Organisms are obtained from empyema fluid in the majority of cases despite prior use of antibiotics; even if they are

**Fig. 14.5** CT image of a left-sided empyema showing the thickened pleural 'rind' (arrow) that surrounds the collection of pus.

**Fig. 14.6** The chest radiograph (a) in this 39-year-old man with an empyema suggested a single laterally placed collection, but the CT image (b), while confirming the main collection, also showed two smaller separate loculations situated anteriorly and posteromedially.

not, the diagnosis of empyema is accepted provided the turbidity is accounted for by cells that are predominantly neutrophil leucocytes [8,11,20,31]. Empyema fluid can be distinguished from pleural fluid that is turbid due to the presence of chyle by the use of centrifugation, in which case a whitish layer of chylomicrons is found on the surface of the pleural fluid [82]. The diagnosis of empyema is also accepted if organisms are obtained from pleural fluid irrespective of its gross appearance.

The visual appearance of the fluid provides clues as to the responsible organism only infrequently, although the

unusual case of *E. histolytica* is well known for its association with 'anchovy sauce' and *Actinomyces* spp. for 'sulphur granules' [83]. The olfactory senses do not have to be highly developed to detect the stench of putrefaction that is peculiarly characteristic of anaerobic infection, which once smelt is never forgotten. In one recent series, empyema fluid was described as malodorous in 62% of cases, anaerobes being recovered from half of these, whereas pneumococcal empyemas rarely smelt bad [11].

Blood cultures were positive in about 7% of one recently reported series [11]. Sputum culture is unhelpful in most cases as the organisms recovered often differ from those isolated directly from the empyema fluid itself [11].

### Biochemistry

Pleural effusions occurring in association with pneumonia

are exudates (see Chapter 43) and may be described as 'parapneumonic'. Work has been carried out to determine whether it is possible to predict from biochemical criteria which minority of these parapneumonic effusions are 'complicated', i.e. will develop into empyemas. Such complicated parapneumonic effusions have been found to have a low pH and glucose and a raised lactate dehydrogenase (LDH) [84]. The results of such measurements may be more pertinent in the opposite sense: effusions that do not meet given criteria are unlikely to become empyemas [85]. Thus if the pH of the pleural fluid is greater than 7.2, the LDH content less than 1000 iu/L and the glucose content either greater than 3.3 mmol/L (60 mg/dL) or in a ratio to blood glucose greater than 0.5, then it is improbable that the effusion will develop into an empyema. The opposite cannot always be relied upon to indicate that a parapneumonic effusion will require management as an empyema, as the pH is less than 7.2 in most 'rheumatoid' effusions and in some neoplastic and tuberculous effusions [86,87]. Pleural fluid glucose may also be significantly lowered in the same situations [88,89]. The reduced pH and glucose levels associated with empyemas may occur as a result of leucocyte and bacterial anaerobic metabolism of glucose, a process that produces lactic acid [86]. The accurate measurement of pleural fluid pH requires anaerobic collection in a heparinized syringe and removal to the laboratory on ice [82], although immediate transfer of an aliquot of the main aspirate to a heparinized syringe appears to be a practical option [90]. It has also been argued that when the pH criteria for the development of an empyema are met, the diagnosis is usually obvious by virtue of pleural fluid turbidity or the demonstration of an organism; furthermore, no prospective randomized trials have been carried out to assess whether drainage based on the biochemical parameters of a parapneumonic effusion improve outcome when compared with drainage based on clinical assessment [91,92].

## Management

There are two basic principles for the successful management of thoracic empyema: (i) control of infection with appropriate antimicrobial therapy and (ii) adequate drainage of pus. Adherence to these principles should return the pleural cavity to its former sterile state and allow full re-expansion of the underlying lung. Although many empyemas are treated entirely satisfactorily without recourse to operative surgical procedures, consultation with an experienced thoracic surgeon is advantageous, may become essential and is advised earlier rather than later in order that a suitable management plan can be agreed.

A prospective multicentre study of 119 patients with empyema found that the size of the empyema had an important influence on whether operative surgical inter-

vention would be required [11]. Medical treatment, comprising antimicrobial agents, aspiration and/or tube drainage, was successful in about 80% of patients in whom the empyema was judged to fill 20% or less of the hemithorax on the radiograph; the success rate for medical treatment fell to 50% for empyemas of intermediate (20–40%) size, and to only 24% in empyemas judged to be large (>40%) [11].

## Antimicrobial therapy

The choice of antibiotic (see Chapter 9) is usually determined from the results of microbiological culture and sensitivity testing.

### Anaerobes

Anaerobic infection may be treated with benzylpenicillin. Because of the increasing problem of penicillin-resistant strains, it is usual to add metronidazole to cover  $\beta$ -lactamase producing Gram-negative anaerobes. Some authors have found a better response when comparing clindamycin with penicillin as this is active against *Bacteroides fragilis* and other penicillin-resistant anaerobes (see Chapter 15) [93]. Metronidazole should not be used alone because some anaerobic cocci and most microaerophilic streptococci (e.g. *Strep. milleri/intermedius* group) are resistant to it.

Many other antimicrobial agents are active against anaerobes *in vitro* but have not been subjected to controlled clinical trials in patients. These apparently effective antibiotics include most but not all  $\beta$ -lactams, activity being particularly augmented by combination with a  $\beta$ -lactamase inhibitor, as in the case of amoxicillin (amoxycillin) and clavulanic acid to produce co-amoxiclav. Similarly, in the USA, ampicillin is available in combination with the  $\beta$ -lactam inhibitor sulbactam.

Other penicillins with activity against anaerobes include the extended-spectrum (antipseudomonal) penicillins such as the ureidopenicillins piperacillin and azlocillin and the carboxypenicillin ticarcillin. These are not usually required for treating empyemas but may sometimes be appropriate when the infection has been acquired in hospital, in which case a mixed flora with Gram-negative aerobes as well as anaerobes is more likely to be encountered. Ticarcillin is also commercially available combined with the  $\beta$ -lactamase inhibitor clavulanic acid, as is piperacillin with tazobactam.

Similarly, imipenem and meropenem, which are carbapenem  $\beta$ -lactams, have excellent *in vitro* activity against anaerobes as well as being active against a wide spectrum of Gram-positive and Gram-negative bacteria including *Ps. aeruginosa*.

Of the cephalosporins, cefoxitin (considered 'second generation' but in fact a cefamycin) is the most potent *in*

*vitro* against the *B. fragilis* group, tending to be relatively resistant to  $\beta$ -lactamases produced by Gram-negative bacilli. Third-generation cephalosporins, for example ceftazidime, and related drugs are less active against anaerobes and better avoided in this clinical setting.

Chloramphenicol is very effective *in vitro* against virtually all anaerobes but, because of its potential for marrow suppression, tends to be used only in life-threatening situations when other therapy is judged to be failing or is unavailable.

Macrolides (such as erythromycin, clarithromycin and azithromycin) are not ideal as single agents as they have poor activity against anaerobic fusobacteria, although this can be offset by combining them with metronidazole.

Tetracyclines are best avoided as significant numbers of resistant anaerobic strains have emerged. Quinolones as a group are also relatively ineffective against anaerobes. Of the other  $\beta$ -lactam antibiotics, aztreonam is ineffective. So are co-trimoxazole (trimethoprim-sulfamethoxazole) and the aminoglycosides, although the latter may be considered as part of a combination regimen to cover Gram-negative aerobic bacilli.

### Pneumococcus

Pneumococcal empyema usually responds to high-dose benzylpenicillin initially, continuing with oral phenoxymethylpenicillin (penicillin V) or amoxicillin. The problem of penicillin-resistant pneumococci is discussed in Chapter 13. Alternatives for penicillin-allergic individuals include a first-generation cephalosporin such as cefradine (cephradine) or a macrolide such as clarithromycin.

### *Staphylococcus aureus*

In the UK, *Staph. aureus* is ordinarily treated with flucloxacillin. This drug is unavailable in the USA where dicloxacillin is marketed for oral treatment and methicillin, oxacillin or nafcillin are available for parenteral use. A first-generation cephalosporin such as cefradine may be used, orally or parenterally, as an alternative antimicrobial in penicillin-allergic patients. Methicillin-resistant *Staph. aureus* presents special problems and is discussed in Chapter 13. It may be treated with the glycopeptide antibiotics vancomycin or teicoplanin (see Chapter 9). When treatment with these single agents fail, gentamicin or rifampicin or both are sometimes added.

### Gram-negative aerobes

Serious Gram-negative aerobic infection may be treated with the combination of a third-generation cephalosporin such as ceftazidime and an aminoglycoside such as gentamicin. When concern exists about the possibility of a mixed infection including both anaerobes and Gram-

negative aerobes, a ureidopenicillin or carboxypenicillin might be a better choice (see above). *H. influenzae* is still usually responsive to amoxicillin, although  $\beta$ -lactamase-producing organisms may require co-amoxiclav, a macrolide such as clarithromycin, or ciprofloxacin as possible alternatives. Adults with empyema who are admitted from the community and in whom the infecting organisms have not yet been identified may be treated initially with a combination that includes a  $\beta$ -lactamase-resistant penicillin such as co-amoxiclav, metronidazole and flucloxacillin, this regimen being modified in the light of cultures and the patient's clinical response. The duration of chemotherapy in patients treated medically is likely to be several weeks and it is prudent to continue drug treatment for at least 3 weeks after all drainage has ceased.

### Tuberculosis and unusual organisms

Tuberculous empyema requires conventional combination chemotherapy (see Chapter 19), although this may need to be continued for longer than the usual 6 months according to sensitivities and response. Eradication of infection will not be achieved without adequate drainage.

The treatment of other more unusual organisms also requires drainage with appropriate antimicrobial chemotherapy. *Aspergillus* may require amphotericin or itraconazole. Cryptococcosis in the immunocompromised patient is treated with amphotericin and flucytosine, the latter being continued as maintenance therapy. Blastomycosis is also treated with amphotericin in patients who are immunocompromised or severely ill, whereas itraconazole is an alternative in less sick patients. Coccidioidomycosis may be treated with amphotericin or itraconazole.

Actinomycosis is treated with high-dose benzylpenicillin followed by prolonged therapy with oral amoxicillin or phenoxymethylpenicillin, whereas tetracycline has been used most widely in penicillin-allergic patients. *Nocardia* may respond to co-trimoxazole, sulfadiazine (sulphadiazine) or imipenem as single agents.

Clostridial empyemas are treated with high-dose benzylpenicillin initially, metronidazole or imipenem being alternatives. Ill patients infected with *Bacillus cereus* may be treated initially with vancomycin, while a combination of doxycycline and rifampicin may be used to control *Bruceella* infection. Benzylpenicillin, amoxicillin and doxycycline are among the drugs usually effective in *Pasteurella multocida* infection. *Salmonella* may be treated with ciprofloxacin or a third-generation cephalosporin such as ceftazidime.

Hydatid infection is generally treated by surgical excision with albendazole cover. Praziquantel is effective against the lung fluke *Paragonimus westermani*. Rare cases of *Trichomonas* empyema may be treated with metronida-

zole. Empyema complicating amoebiasis is treated with metronidazole and diloxanide furoate.

Drug therapy for *Burkholderi cepacia* is based on sensitivities but strains may be susceptible to ureidopenicillins, third-generation cephalosporins, co-trimoxazole, ciprofloxacin and chloramphenicol.

## Drainage

Drainage of an empyema may be closed or open (Fig. 14.7) and the technique used depends on the stage of the empyema (see above) at the point of intervention.

### Closed drainage

Closed drainage may be either 'intermittent', in which repeated aspiration (thoracentesis) is carried out, or 'continuous', in which an intercostal tube is connected to an underwater seal (closed-tube thoracostomy). Closed drainage is preferred provided that the pus is accessible and not too viscid to permit adequate removal by these methods. These conditions are more likely to appertain in the exudative stage but can be continued into the fibrino-purulent stage in some cases.

### Thoracentesis

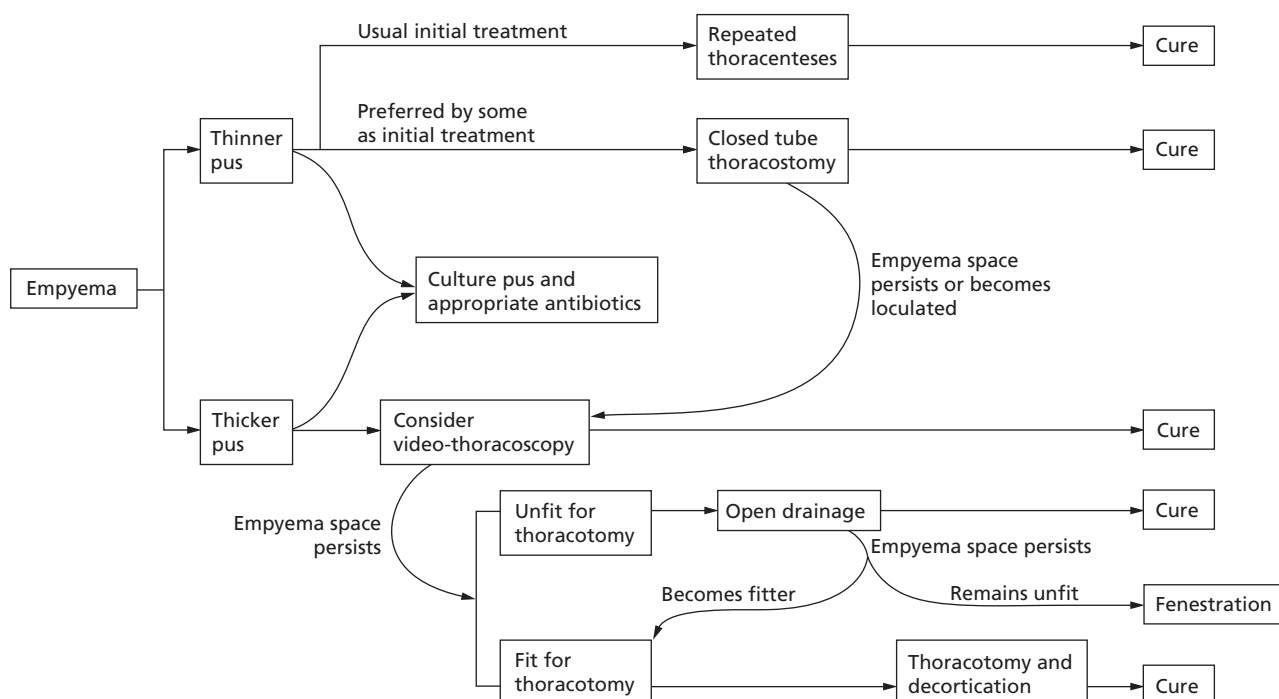

The site of the pus can often be confirmed with the local

anaesthetic needle. Aspiration is thereafter best carried out using a needle or cannula of sufficient bore to allow the pus to flow without too much exertion on the part of the operator. Sharp needles are best avoided for fear of damaging underlying lung. The use of an Abrams punch biopsy needle is useful initially, as it is of sufficiently wide calibre to allow easy aspiration and also permits diagnostic biopsy of the parietal pleura/empyema cortex for histological examination and culture. The frequency with which thoracentesis is repeated depends upon the rate at which pus reaccumulates, which in turn is judged by the clinical and radiographic findings. Aspiration may be required daily or two or three times per week at first, diminishing as infection responds to antibiotics, and may sometimes extend over a prolonged period, during which time the patient is usually ambulant and visits the hospital as an outpatient. Such medical treatment with antibiotics and repeated thoracentesis is appropriate for many individuals with pleural empyema and these patients may have a shorter and less complicated stay than those treated by tube drainage [94].

### Closed-tube thoracostomy

Closed-tube thoracostomy is preferred by some clinicians from the start once the diagnosis of empyema has been confirmed [85,94]. It has the advantages that drainage is continuous and that it is more likely to be successful when the infected material is too viscid to be removed by manual aspiration, but with the disadvantage of greater discomfort and immobility for the patient; furthermore,

Fig. 14.7 Management of empyema.

introduction of new infection at the drainage site is a possibility and the tube itself may become blocked by fibrin [95]. Malécot-type self-retaining soft rubber catheters have advantages over the modern disposable rigid plastic cannulae in widespread use, in that underlying structures are less likely to be impaled during introduction, they can be made to fit the cutaneous incision snugly with less chance of leakage around the tube and they are less likely to fall out [96]. Regrettably, however, they are no longer available in most centres. Under local anaesthesia the tube is placed in the most dependent part of the empyema cavity, a site that may be determined by ultrasound examination, CT or the injection of a little radio-opaque contrast material. Ultrasound may also be used to place a small catheter (such as an 8 French gauge pigtail nephrostomy tube with 10 side-holes) in larger loculations and this may be connected to a plastic drainage bag attached to the chest wall. Patency may be maintained using streptokinase (see below).

When underwater seal drainage through a conventional large-bore intercostal tube becomes slight, the tube may be cut off, transfixed with a safety pin (to prevent it falling into the empyema cavity) and covered with a gauze dressing to allow the patient greater mobility until it is removed. Sinography may be carried out by injecting contrast down the tube in order to assess the adequacy of drainage [97]. When the residual sinus is small and drainage minimal (e.g. <150 mL daily for two consecutive days, including 6-hourly 20-mL saline flushes), the tube is removed.

A technique somewhere between thoracentesis and closed-chest drainage has been described in which a 20–28 French gauge plastic cannula is passed into the empyema cavity under local anaesthesia using ultrasound control, fibrinous septa being broken down and pus rapidly removed by strong negative pressure (–13 kPa), after which the cannula is removed and the skin resutured [98].

### *Fibrinolytic and irrigation therapy*

The instillation of antiseptics, antibiotics and fibrinolytic agents has long been practised in order to attempt to sterilize the contents of the empyema cavity and to break down fibrinous loculations that contain pus [99–101]. ‘Irrigation therapy’ was reported to be effective in 1876 and although it continues in use in different centres and in various forms, it remains controversial [102–104]. The use of streptokinase as an intrapleural fibrinolytic to break down fibrin bands in order to allow loculae to drain more freely was reported in 1949 [105]. The technique was abandoned due to allergic reactions, only to be taken up again with the availability of purer commercial preparations of streptokinase, urokinase also being sometimes used [106–108]. A recent small, randomized, controlled trial examined the effect of once-daily streptokinase on closed-tube thoracos-

tomy [109]; 12 patients with infected parapneumonic effusions or empyemas were assigned to receive 6-hourly 20-mL normal saline flushes via a 14 French gauge intercostal drain that had been placed by a radiologist under ultrasound guidance; 12 further patients received the same 6-hourly flushes, one of which contained 250 000 units of streptokinase that was started at the time of diagnosis and given for three consecutive days, the catheter being clamped for 2 h after the streptokinase before being returned to suction. The fluid was overtly purulent in only 11 of the 24 patients. All patients received antibiotics and the catheter in each patient was connected to an underwater drain and kept on 2 kPa [20 cmH<sub>2</sub>O] suction [109]. The protocol allowed drains to be removed after the fifth day of treatment provided that drainage had fallen to less than 150 mL daily, including flushes, for two consecutive days. The duration of hospital stay was similar for the two groups but a larger volume of drainage and greater chest radiographic improvement at discharge was achieved in the streptokinase group, none of whom required surgical referral, whereas three of the control group did [109]. Although this suggests that the technique may improve the drainage of infected or potentially infected material from the pleural space, further work is required to confirm the safety and efficacy of intrapleural fibrinolytics in improving key outcomes, such as the need for open surgical drainage, length of hospital stay and mortality [110,111]. Total doses of up to 1.5 million units of intrapleural streptokinase given over 3 days do not appear to cause significant activation of systemic fibrinolysis [112], although there are isolated reports in the literature of life-threatening *local* haemorrhage that may lead to thoracotomy [113,114].

Closed drainage, whether by thoracentesis or intercostal tube, is likely to be successful if the empyema is small [11] and if treatment of the empyema is started in the acute exudative or early fibrinopurulent stages of infection, in which case the wall of the empyema cavity gradually becomes reabsorbed allowing re-expansion of underlying lung and obliteration of the pleural space. This process can be expected to take several weeks in adult practice. Bronchoscopy is recommended following the successful conclusion of closed drainage in order to exclude any possible endobronchial causes of obstruction, such as tumour or foreign body. High resolution CT may be used if underlying bronchiectasis is thought likely.

The techniques outlined above may fail to cure an empyema if the pus is too thick to drain by thoracentesis or tube, if a bronchopleural fistula has developed or if pockets of pus become loculated and inaccessible. When closed drainage has failed to enable the lung to re-expand fully, a more invasive surgical procedure has to be employed. Such procedures include thoracoscopy, open drainage with rib resection, thoracotomy and decortication and, rarely, thoracoplasty.

### Video-assisted thoracoscopic surgery

If closed drainage does not result in prompt re-expansion of the lung and especially if loculi have been identified ultrasonically, a decision to intervene relatively early using video-assisted thoracoscopic surgery (VATS) with débridement and drainage is sometimes made. A small prospective randomized controlled trial in patients with fibrinopurulent empyema has compared treatment by VATS with fibrinolytic therapy using chest-tube pleural drainage and streptokinase; this showed that VATS was more effective, with faster resolution and a shorter hospital stay than that achieved with fibrinolytic therapy [115]. Provided that the empyema is in the fibrinopurulent stage, with the thickened rind caused by fibrin rather than the mature scar tissue that forms when an empyema has become chronic, VATS enables the operator to achieve adequate débridement, breaking down loculi, evacuating pus and debris and freeing the lung. This may then result in prompt re-expansion of the lung and obliteration of the pleural cavity, avoiding the need for repeated or prolonged attempts at drainage [116,117].

### Open drainage

Open surgical drainage is used if an empyema persists both clinically and radiographically in a patient in whom closed drainage has proved unsuccessful. It may be avoided if the empyema is suitable for drainage by VATS. When VATS is unavailable, unsuccessful or considered inappropriate, open drainage may be carried out in patients whose general condition is such that they are judged to be too debilitated to undergo the more invasive procedure of thoracotomy and decortication. Open drainage, which has been carried out in a sitting position under local anaesthetic to avoid spread of sepsis to the unaffected lung, often involves resection of the lowest rib above and below which pus can be aspirated [96]. The surgeon makes an incision large enough to allow adequate drainage, cleans the inside of the empyema cavity and places a wide-bore tube surrounded by gauze in the unsutured wound. Daily redressing under surgical supervision with sterilization and replacement of the tube is recommended. Successful open drainage results in gradual obliteration of the empyema space, which allows ultimate removal of the tube and cure. Thoracotomy and decortication (see below) may still be recommended if, during open drainage, the patient's general condition improves sufficiently.

When drainage is protracted and the patient remains too ill or is otherwise unsuitable for thoracotomy, then a more permanent fenestration or open-window thoracotomy (sometimes referred to as an Eloesser flap) may be performed. Such procedures involve the removal of sections of two or more ribs in order to fashion a larger

stoma, which is kept open by suturing the skin to the parietal pleura/cortex thereby creating a pleurocutaneous fistula [96]. The stoma may be closed if the underlying lung re-expands or may occasionally be left permanently open with daily dressing changes. Fenestration procedures are sometimes used in empyemas that complicate pneumonectomy. This form of empyema is often associated with a bronchopleural fistula through the bronchial stump. These fistulae, if small, may close spontaneously but if large do not close without a surgical procedure, such as resuturing with or without the transposition of pediculated intercostal muscle in order to cover the bronchus and also to help obliterate the empyema space [96]. A persistent bronchopleural fistula in this situation prevents successful closure of the fenestration [118,119].

### Decortication

This is an elective surgical procedure, unsuitable for patients who are ill and toxic, in which the fibrous wall of the empyema cavity, variously referred to as the cortex, rind or peel, is exposed at thoracotomy and stripped off the adjacent visceral and parietal pleura, which may be left intact. A bronchoscopy is carried out first in non-traumatic cases to exclude an underlying tumour or foreign body [96]. Decortication is carried out in patients in whom closed drainage and/or thoracoscopic methods have been unsuccessful, provided that they are fit enough to undergo this major procedure. It may also be used in the patient whose condition has stabilized following open drainage but who has entered a chronic phase in which the underlying lung does not expand because of failure of the cortex or rind to become reabsorbed. There is no consensus about the optimal time at which to perform a decortication, some surgeons arguing for early intervention and others adopting a more conservative approach [120–122]. In the early stage of organization the empyema cortex is poorly demarcated and friable, making decortication difficult. In intermediate stages of formation it is rather vascular so that decortication may be best delayed 2 or 3 months in order to reduce morbidity. It should not be forgotten that the cortex surrounding an empyema cavity does have a capacity to resolve spontaneously, albeit over a number of months, so that surgical decortication may be avoided altogether [123].

Heavily calcified chronic empyemas may occur in 'old' inadequately treated tuberculosis. These may be technically impossible to decorticate and if silent are best left alone. Where they point and discharge through the skin (empyema necessitans, see above and Fig. 14.3) surgical dilatation of the fistulous track or tracks may assist drainage, which can be collected in colostomy bags. When more radical surgical intervention is necessary in these cases, such as following the development of a

bronchopleural fistula, pleuropneumectomy may be required [34,96].

## Thoracoplasty

Thoracoplasty was once widely practised as a surgical management for cavitary tuberculosis, but is now used only rarely in order to (i) obliterate an empyema space fol-

lowing pneumonectomy or (ii) manage a persistent empyema cavity in patients where extensive ipsilateral parenchymal lung disease would prevent re-expansion after decortication and in whom extrapleural pneumonectomy would be unacceptably hazardous [124]. Thoracoplasty is a mutilating procedure that produces a grotesque chest wall deformity but is nevertheless still sometimes used as a last resort.

# LUNG ABSCESS

DOUGLAS SEATON

A lung abscess is a localized area of destruction of lung parenchyma in which infection by pyogenic organisms results in tissue necrosis and suppuration. Lung abscesses may be single or multiple and they frequently contain air–fluid levels. When multiple and small (<2 cm in diameter) they are sometimes referred to as necrotizing or suppurative pneumonia, but they are an expression of the same pathological process and the distinction is an arbitrary one. It should not be forgotten that in addition to the more usual anaerobic and aerobic organisms, lung abscesses may also be found in tuberculosis (Chapter 17) and may be caused by non-bacterial organisms including fungi and protozoa (Chapters 21 & 22). Similar radiographic appearances may also be produced by other pathologies such as necrosis in a lung tumour or infection within a lung cyst.

## Mechanisms of infection

There are several ways in which pyogenic infection may reach the lung (Table 15.1) but by far the most important of these and the commonest cause of lung abscess is the aspiration of oropharyngeal contents [1].

### Aspiration

Saliva is particularly rich in anaerobic bacteria, the concentration of which may reach  $10^8$ /mL in healthy people. These count rates may be increased 1000-fold in subjects with dental or periodontal sepsis and about 350 different bacterial species have been encountered [2,3]. Various aerobic pyogenic organisms may also colonize the mouths of susceptible individuals. Radioactive tracer techniques have been used to show that small amounts of saliva are aspirated into the lungs during sleep in 45% of healthy people and in 75% of patients whose level of consciousness is depressed for various reasons [4]. Patients who are particularly liable to aspirate their oropharyngeal contents include those whose conscious level and cough reflex is impaired as a result of general anaesthesia, excessive

alcohol or other sedative drugs, head injury, cerebrovascular accidents, epileptic seizures, diabetic coma or other prostrating illness, including those resulting in mechanical ventilation on intensive care units. Although this last group of patients have cuffed endotracheal or tracheostomy tubes in place, it is clear that some of the secretions that pool above the cuffs find their way into the lower respiratory tract. When the level of consciousness is depressed in any of these situations, stomach contents may be aspirated and the low pH can cause a chemical pneumonitis that is probably an important predisposition to bacterial infection [5]. Spill-over into the trachea is also favoured by abnormalities of deglutition, whether these are mechanical, as in benign or malignant oesophageal strictures, or due to neuromuscular dysfunction, as in bulbar palsy or oesophageal achalasia.

The presence of dental sepsis or gingivitis increases the likelihood of aspiration pneumonitis and lung abscess as does dental extraction under general anaesthesia, due to the high content of anaerobic bacteria in the saliva of many of these patients [2,6]. Conversely, only 10–15% of patients with anaerobic lung abscesses have no obvious periodontal disease or other predisposition to aspiration [7]. It is of note that lung abscesses are seldom found in edentulous patients and carcinoma of the lung should be suspected when they are.

Further support for the importance of aspiration of oropharyngeal contents in causing the necrotizing pneumonia that may lead to lung abscess formation is provided by the observation that 75% of such abscesses occur in the posterior segment of the right upper lobe or the apical segments of either lower lobe, these being the segments to which aspirated material has been shown to gravitate in the supine subject [6,8].

The likelihood of an abscess developing following aspiration is probably influenced by the quantity, bacterial content and pH of the material aspirated, and the quality of the patient's lung defences. The latter includes both mechanical clearance and cellular and humoral competence, patients taking corticosteroids or other immuno-

**Table 15.1** Factors predisposing to lung abscess.**Aspiration of oropharyngeal flora**

Dental/periodontal sepsis  
 Paranasal sinus infection  
 Depressed conscious level  
 Alcohol/sedative drug abuse  
 Anaesthesia  
 Epilepsy  
 Head injury  
 Cerebrovascular accident  
 Diabetic coma  
 Other prostrating illness  
 Impaired laryngeal closure  
 Cuffed endotracheal tube  
 Tracheostomy tube  
 Recurrent laryngeal nerve palsy  
 Disturbances of swallowing  
 Oesophageal stricture (benign or malignant)  
 Oesophageal motility disorders, e.g. systemic sclerosis  
 Neuromuscular disease, e.g. bulbar/pseudobulbar palsy  
 Achalasia  
 Pharyngeal pouch  
 Neck surgery  
 Delayed gastric emptying/gastro-oesophageal reflux/vomiting

**Necrotizing pneumonia**

*Staphylococcus aureus*  
*Streptococcus milleri/intermedius*  
*Klebsiella pneumoniae*  
*Pseudomonas aeruginosa*

**Haematogenous spread from a distal site**

Urinary tract infection  
 Abdominal sepsis  
 Pelvic sepsis  
 Infective endocarditis (right-sided)  
 Intravenous drug abuse  
 Infected intravenous cannulae  
 Septic thrombophlebitis

**Pre-existing lung disease**

Bronchiectasis  
 Cystic fibrosis  
 Bronchial obstruction  
 Tumour  
 Foreign body  
 Congenital abnormality

**Infected pulmonary infarct****Trauma****Immunodeficiency**

Primary or acquired

claimed that patients receiving this type of medication as prophylaxis against 'stress' peptic ulceration while in the intensive therapy unit are more likely to develop lung sepsis due to aspiration than those receiving sucralfate (which has little antacid activity) for the same purpose [9,10].

**Other mechanisms**

Other mechanisms are less common and include blood spread. This sometimes occurs when there is a focus of Gram-negative sepsis elsewhere, such as in the urinary tract, possibly following catheterization or urethral instrumentation, or in the abdominal or pelvic cavities [11,12]. Anaerobic infection may also spread haematogenously from intra-abdominal, pelvic or even periodontal sepsis and lung abscesses may also complicate staphylococcal bacteraemia [13–15].

Septic emboli may reach the lungs from right-sided bacterial endocarditis, which most commonly complicates intravenous drug abuse (Fig. 15.1), the usual organism being *Staphylococcus aureus* (see below). Septic emboli may also arise from infected intravenous cannulae or from thrombophlebitis arising in the deep veins of the legs or pelvis or in relation to superficial cutaneous cellulitis [16]. The infected thrombi may contain *Staph. aureus*, *Streptococcus pyogenes* or anaerobes. A bizarre case of septic embolism has been described in a patient with Münchhausen's syndrome following intravenous self-injection of faeces [17].

Colonization of the lower respiratory tract with pyogenic organisms may occur in patients who have chronic lung disease such as bronchiectasis or cystic fibrosis, both of which may be complicated by lung abscess formation [18,19].

The inhalation of aerosolized bacteria is an unusual way for lung abscesses to arise other than as a consequence of tuberculosis. *Legionella* species may cause lung abscess but only rarely. Contaminated respiratory equipment such as nebulizers possess the potential to carry pyogenic organisms to the lungs of susceptible patients, and chemically induced lung abscesses have been described in itinerant paraffin-breathing fire-eaters [20,21].

The development of lung abscesses is also favoured by conditions that prevent normal clearance of pulmonary secretions, such as lung tumours, bronchiectasis and inhaled foreign bodies, the last situation particularly applying to children [22]. Lung cancer itself may cavitate and become infected. Secondary infection may also occur in congenital abnormalities such as bronchopulmonary sequestrations and lung cysts (see Chapter 50), which may be indistinguishable from primary lung abscesses in the absence of previous radiographs. Areas of thromboembolic pulmonary infarction may similarly cavitate and become infected, with resultant abscess formation [16].

suppressing agents being more vulnerable. Finally the presence of coexisting lung disease and the speed with which infection is recognized and treated appropriately are clearly relevant.

Oropharyngeal colonization with Gram-negative bacilli has been found to be more common in subjects treated with histamine H<sub>2</sub>-receptor blockers and it has been

**Fig. 15.1** Multiple lung abscesses (arrows) in a 27-year-old intravenous heroin addict with septic embolization arising from *Staphylococcus aureus* tricuspid valve endocarditis caused by self-injection of heroin into the right femoral vein. Complete resolution followed a 4-week course of intravenous flucloxacillin.

## Microbiological characteristics

Lung abscesses may be caused by a wide variety of different organisms and it is common to obtain a mixed bacterial growth from a single abscess when the pus is cultured. When lung abscesses have followed overt tracheo-bronchial aspiration, the frequency with which particular organisms or groups of organisms are found is related to whether the infection was acquired in the community or in hospital (see Chapter 13). Thus anaerobes only were isolated in 69% of community-acquired cases, whereas in hospital-acquired cases anaerobes were obtained in pure culture in only 7% of cases, other organisms such as *Staph. aureus*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* playing a major role [23]. Mixed aerobic and anaerobic infections were found in 92% of all cases.

## Anaerobic organisms

Anaerobes are the group most frequently implicated. One published series of 93 lung abscesses recorded microbiological recovery of anaerobes in 89% of cases by the now seldom used transtracheal aspiration technique (see Chapter 8) [24]. Aerobic organisms were also recovered in 43% of all cases. Another study, in which 50 consecutive cases of 'chronic destructive cavitary pneumonia' were investigated by invasive microbiological methods, recorded a recovery rate for anaerobes of 60% and for aerobes of 80% of the total, 54% of infections being mixed [25]. The diagnostic techniques in this study included percutaneous lung puncture, transtracheal aspiration and open lung biopsy. When anaerobes are recovered from lung abscesses it is common for many different organisms

to be found [26]. This accords with the multiplicity of anaerobes recoverable from the oropharynx [2,3]. One large series of 193 patients collected over 7 years documented the involvement of 461 strains of anaerobic bacteria. In about half of these patients anaerobes were recovered in pure culture, while in the remainder anaerobes combined with aerobes or facultative anaerobes [27]. In a review of six series of patients with lung abscess the author found the incidence of anaerobic bacterial infection to be 85–93% [27].

The main groups of anaerobes are as follows.

- 1 Gram-negative bacilli making up the genus *Bacteroides*, notably *Bacteroides fragilis*. To add to the clinician's difficulties, the taxonomists have consigned some strains of what used to be called *B. melaninogenicus* to two new genera, *Prevotella* and *Porphyromonas*.
- 2 Gram-positive cocci, mainly *Peptostreptococcus* and anaerobic or microaerophilic streptococci.
- 3 Long thin Gram-negative rods comprising *Fusobacterium* species, particularly *F. nucleatum* and *F. necrophorum*.

## Aerobic organisms

Aerobic organisms tend to cause lung abscesses as part of a necrotizing pneumonia that can be seen to be radiographically more diffuse than is the case with classical anaerobic lung abscess, in which the surrounding lung parenchyma may appear relatively normal on the chest film. A possible exception to this is the *Strep. intermedius* group (also known as *Strep. milleri*), comprising *Strep. intermedius*, *Strep. constellatus* and *Strep. anginosus*, all belonging to the viridans group of streptococci. Isolates of

*Strep. intermedius* may be mistaken for anaerobic streptococci as they require carbon dioxide and may grow better under microaerophilic or anaerobic conditions. *Strep. intermedius* is the most common viridans species associated with pyogenic infection [28–30], and was the commonest single isolate (aerobic or anaerobic) in one study of lung abscess and empyema [26]. Notably, the viridans group of streptococci (unspciated) was also the most common isolate in a series of ‘chronic destructive pneumonia’ containing a high proportion of cavitation [25].

### Gram-positive aerobes

*Staph. aureus* is one of the major Gram-positive aerobic organisms to be implicated in lung abscess formation (see also Chapter 13). This may be acquired as a respiratory pathogen in the community, typically causing severe pneumonia following influenza in previously healthy individuals, and may result in the formation of lung abscesses and thin walled cyst-like spaces known as pneumatoceles that are sometimes seen in adults but which occur particularly in infants, *Staph. aureus* being the leading cause of lung abscess in children [31]. *Staph. aureus* also not uncommonly occurs in older adults as a hospital-acquired complication of coexisting illness [32]. Lung abscesses caused by this organism may result from blood-borne spread of infection from septic foci elsewhere, including endocarditis of the tricuspid valve in intravenous heroin abusers [33]. This haematogenous spread typically produces multiple pulmonary infiltrates (see Fig. 15.1) and these may sometimes mimic pulmonary metastases when the infection has arisen from a central line in patients receiving chemotherapy for neoplastic disease [34].

Other Gram-positive aerobes rarely cause lung abscesses. *Strep. pyogenes* (syn. Group A streptococcus,  $\beta$ -haemolytic streptococcus) used to be a very common cause of suppurative pneumonia before penicillin and its derivatives became widely available, particularly affecting children after viral and other upper respiratory tract infections but also adults, notably after influenza [35]. There appears to have been something of a resurgence of reports of invasive *Strep. pyogenes* infections in recent years, once again often with a history of preceding upper respiratory tract infection [36,37]. *Strep. pneumoniae* (see also Chapter 13) does not ordinarily cause lung abscess, although this complication has occasionally been recorded, notably with serotype 3.

### Gram-negative aerobes

The most common Gram-negative aerobe to cause necrotizing pneumonia associated with lung abscess is *K. pneumoniae*, at one time known as Friedländer’s bacillus. *Klebsiella pneumoniae* (see Chapter 13) is associated with

one or more abscesses in over 25% of cases and may also be associated with bacteraemia. It will be overdiagnosed if sputum culture alone is relied upon for, as is often the case with other isolates, this may merely reflect oropharyngeal colonization. It has a high mortality, with an apparent predilection for elderly and infirm patients and those receiving cytotoxic chemotherapy or corticosteroids. It is seemingly also more common in diabetics [38].

*Ps. aeruginosa* attacks a similar population, immunosuppressed patients and those with serious coexisting disease being particularly susceptible. In *Pseudomonas pneumonia* (see Chapter 13), abscesses are usually multiple and small, occurring as part of a patchy necrotizing process.

Lung abscesses resulting from necrotizing pneumonia caused by other Gram-negative aerobes, such as *Haemophilus influenzae*, *Escherichia coli*, *Acinetobacter* species, *Proteus* species and *Legionella* species, may occur but are unusual [39–42].

### Other less usual causes

Tuberculosis and other non-tuberculous mycobacterial infection may result in fluid-filled cavities, particularly in the upper lobes or the apical segments of the lower lobes [43,44].

Fungal infections (Chapter 21) that sometimes produce fluid-filled cavities in the lungs of immunocompetent hosts from endemic areas include chronic pulmonary histoplasmosis (*Histoplasma capsulatum*) [45], blastomycosis (*Blastomyces dermatitidis*) [46] and coccidioidomycosis (*Coccidioides immitis*) [47]. Reactivation of infection by these organisms may occur in patients with immune deficiency, including those with positive human immunodeficiency virus (HIV) serology. However, the most important fungal pneumonias occurring in the immunocompromised host result from infection with *Aspergillus* species and *Cryptococcus neoformans*, both of which may result in cavitation and abscess formation [48,49]. Uncommon fungal opportunists in the immunosuppressed patient include *Candida* species [50], and members of the order Mucorales causing the group of diseases known as mucormycosis (syn. zygomycosis, reflecting the class name of these fungi) [51]. Rarely *Pseudoallescheria boydii* and *Dactylaria constricta* may cause localized lung sepsis [52,53]. The main risk factors for all the opportunist fungal infections are neutropenia, corticosteroid use and HIV infection.

Single large lung abscesses may occasionally occur in pulmonary actinomycosis (Chapter 21), usually caused by the Gram-positive branching bacterium *Actinomyces israeli*, although other species belonging to the same genus may also be implicated. This infection usually causes a lung infiltrate containing a honeycomb of small abscess cavities that may communicate with the chest wall, with bony destruction and sinus formation [54–56]. *Actino-*

*myces* are often microaerophilic but tend to grow best anaerobically. Other genera within the same order Actinomycetales include *Arachnia* and *Nocardia*. These may cause chronic pulmonary disease, and both single and multiple lung abscesses are described in nocardiosis [57].

Pulmonary botryomycosis (bacterial pseudomycosis) is a term applied to a rare condition in which there is an unusual tissue response to infection, with some histological features resembling actinomycosis. It may arise as a response to a variety of infecting organisms, including Gram-positive cocci (*Staph. aureus*, *Streptococcus* species) and Gram-negative bacilli (*Pseudomonas* and *Proteus* species, *E. coli*). Although botryomycosis is more commonly found in the skin and subcutaneous tissues, visceral involvement may occur and single large or multiple small abscesses may be found in the lungs. The diagnosis depends upon histology. It has been described in previously normal hosts as well as in patients with pre-existing disease, including HIV infection and cystic fibrosis [58,59].

Other rare causes of lung abscess documented in immunocompetent patients include pneumonic plague (*Yersinia pestis*) [60,61], *Salmonella* infection [62,63], *Pasteurella multocida* infection [64], *Lactobacillus casei* infection [65], *Strep. mitis* (also of the viridans group) infection [66], brucellosis (*Brucella abortus*) [67] and pulmonary anthrax (*Bacillus anthracis*), although the main thoracic feature of anthrax is haemorrhagic mediastinitis with necrosis and oedema of the hilar lymph nodes [68,69]. Lung abscesses of protozoan origin, typically containing a 'chocolate' exudate, may occur in invasive amoebiasis (*Entamoeba histolytica*) [70]. Melioidosis (*Ps. pseudomallei*) is endemic, particularly in South-East Asia, and may cause pneumonic upper lobe infiltrates that may cavitate and simulate tuberculosis, suppuration sometimes occurring [71].

In the immunosuppressed patient, many organisms that are not usually pathogenic or are usually of low virulence may become implicated in sepsis. *Rhodococcus* (formerly *Corynebacterium*) *equi*, a variably acid-fast Gram-positive bacillus, is one example of such an opportunist that usually causes slowly progressive cavitating pneumonia in immunosuppressed patients, particularly those with AIDS [72]. Another example is *Alcaligenes xylosoxidans*, a Gram-negative rod [73].

## Pathology

Lung abscesses begin as areas of pneumonia in which small zones of necrosis (or microabscesses) develop within the consolidated lung. Some of these areas coalesce to form single or sometimes multiple areas of suppuration that, when they reach an arbitrary size of 1–2 cm in diameter, are customarily referred to as abscesses.

If the natural history of this pathological process is interrupted at an early stage by appropriate antimicrobial

treatment, then healing may be complete with no residual radiographic evidence of damage. However, if treatment is delayed or inadequate, the inflammatory process may progress, entering a more chronic phase. Bronchi adjacent to the area of inflammation may become eroded so that part of the purulent contents of the abscess may be expectorated as foul sputum. Fibrosis may occur in and around the abscess cavity, which may become loculated and walled off by dense scar tissue. With such loculation, drainage of one part of the abscess may occur into a bronchus only for further suppuration to develop in another part. Spillage of pus into the bronchial tree may also serve to disseminate infection either to other parts of the same lung or to the opposite lung.

The extent to which this suppurative process continues can be checked by antibiotics. These may sterilize the abscess cavity so that granulation tissue forms over the fibrous tissue, this then becoming covered by squamous or ciliated columnar epithelium that grows in from adjacent bronchi [74]. It has been shown bronchographically that an epithelialized cavity such as this may have several bronchial communications. The ready availability of antibiotics has made extensive damage of this type exceptional in communities with fully developed health services.

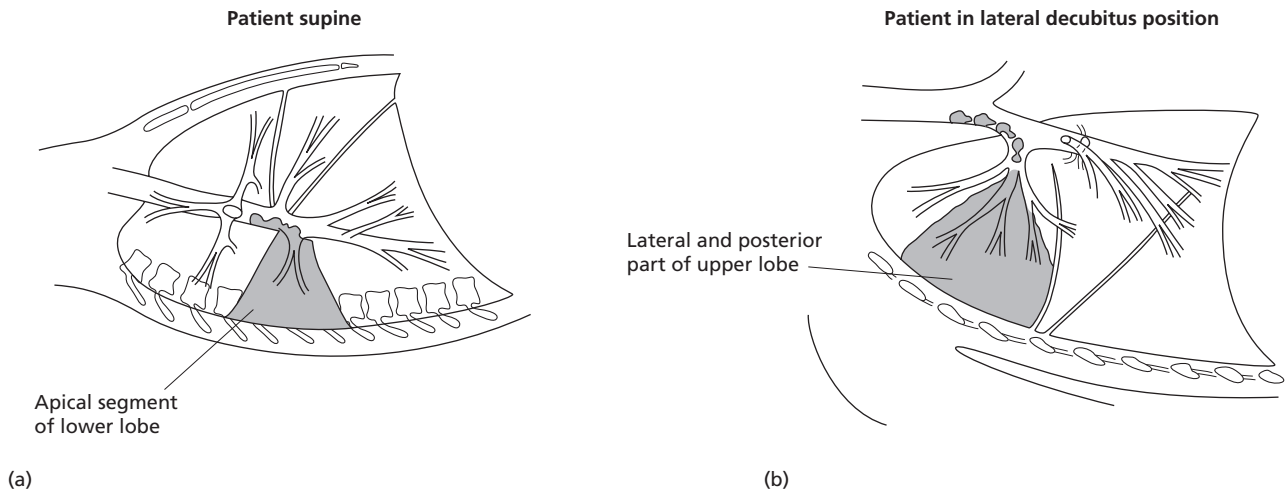

Abscesses arising as a result of aspiration usually occur close to the visceral pleural surface in dependent parts of the lungs. This was demonstrated by Brock over 40 years ago when he introduced small amounts of iodized oil into the tracheas of subjects in various postures. Three-quarters of lung abscesses occur in the posterior segment of the right upper lobe or the apical segments of either lower lobe, the anatomical disposition of these segmental bronchi accepting the passage of aspirated liquid in the supine position most readily [6,8] (Fig. 15.2). Following the same principle, in his classic surgical monograph Brock [6] also engagingly described the case of a coal-heaver with gross periodontal infection who developed a middle lobe abscess supposedly as a result of occult oropharyngeal aspiration occurring in his usual stooped working posture (Figs 15.3 & 15.4).

Despite the close proximity of lung abscesses to the visceral pleura, spread of infection through this membrane with resultant empyema is not the rule, occurring in less than one-third of cases [75]. Lung abscesses that occur as a result of haematogenous spread may be found in any part of the lungs (see Fig. 15.1).

## Clinical features

### Symptoms

The presenting features of lung abscesses vary considerably. Firstly, there may be symptoms of any associated disease process, such as bronchial obstruction due to lung

**Fig. 15.2** Relationship between posture and focal incidence of lung abscess. When the patient is lying supine (a) the apical segment of the lower lobe is vulnerable; when the patient is in the lateral decubitus position (b) the upper lobe is affected. (From Brock [6].)

cancer, oesophageal obstruction due to achalasia, right-sided endocarditis, and so forth (see Table 15.1). Secondly, the clinical picture is influenced by the manner in which the abscess has arisen. The abscess may arise as a result of presumed aspiration in a predisposed host, in which case a history suggestive of this event may be obtained. Such patients are commonly less acutely ill than might be the case in more typical bacterial pneumonia, presumably because the aspirated material contains organisms of relatively low-grade pathogenicity. There may follow an illness of insidious onset with subacute symptoms that may not be sufficiently severe to warrant hospital admission until 2 weeks or longer has elapsed; indeed the patient may be taken aback and resistant to the offer of hospital admission [6]. A few patients may have particularly indolent presentation extending over weeks or months, with constitutional upset, weight loss and symptoms of anaemia [1,76]. The predominant symptoms are usually cough with purulent sputum, fever (sometimes with chills and rigors), dyspnoea and chest pain [77]. The chest pain may be pleuritic or it may be a more deep-seated aching discomfort. There may be large amounts of purulent sputum once a bronchial communication has been established and a putrid smell is indicative of anaerobic infection. Haemoptysis is not uncommon and can occasionally be life-threatening [78]. A subacute onset may also be found in patients who are intravenous drug abusers presenting with septic pulmonary infarcts (usually *Staph. aureus*), typically arising from endocarditis of the tricuspid valve (see Fig. 15.1).

The subacute presenting symptoms associated with presumed aspiration need to be distinguished from massive, often witnessed, aspiration such as might occur

**Fig. 15.3** Occupational posture adopted by a coal-heaver who had gross periodontal disease and who presented with a middle lobe abscess similar to that shown in Fig. 15.4. (After Brock [6].)

during cardiopulmonary resuscitation, in which the immediate pulmonary problem is chemical injury from acid gastric contents, leading to lung infiltrates and possible adult respiratory distress syndrome. This may or may not be followed some days later by pulmonary infection.

The illness also tends to be more abrupt and severe when lung abscesses arise as a consequence of necrotizing pneumonia caused by predominantly aerobic organisms (e.g. *Staph. aureus* or *K. pneumoniae*). Such more acute illness may sometimes be fulminating so that symptoms attributable to abscess formation are usually lost in the more severe symptomatology of the pneumonia itself.

### Signs

There are no signs specific for lung abscess. Digital clubbing may develop within a few weeks if treatment is inadequate. Dullness to percussion and diminished breath

**Fig. 15.4** (a) Chest radiograph of a 34-year-old man with an eating disorder and suspected self-induced vomiting showing *Streptococcus anginosus* abscess in the right middle lobe. (b) CT of the same patient showing the middle lobe abscess but also pneumonic changes in the apical segment of the right lower lobe.

sounds may be present if the abscess is large and situated near the surface of the lung. There may be evidence of associated consolidation and a pleural friction rub is sometimes heard. The 'amphoric' or 'cavernous' breath sounds traditionally associated with lung cavities are rarely elicited in modern practice. There may be signs of an associated pleural effusion, empyema or pyopneumothorax.

## Investigation

The blood count characteristically shows a neutrophil leucocytosis, the white cell count often exceeding  $20 \times 10^9/L$ . A mild normochromic normocytic anaemia may be a feature if the history has been prolonged. The erythrocyte sedimentation rate and plasma viscosity are likely to be raised in non-specific fashion. Sputum may be submitted for cytological examination if a cavitating carcinoma enters into the differential diagnosis.

## Radiography

The radiographic abnormality may start with a pneumonic infiltrate (see Fig. 13.14), followed by the development of one or more spherical areas of more homogeneous density in which air–fluid levels often arise, indicating the formation of a bronchial communication (Figs 15.4 & 15.5). The abscess cavities may be large and are sometimes multilocular with several different fluid levels within one opacity. At other times a pneumonic infiltrate is found to contain numerous small areas of rarefaction, so-called necrotizing pneumonia. Bulging of an interlobar septum

in such cases is said to be a feature of *Klebsiella* infection, which tends to affect the dependent segments, as is the case with other forms of lung abscess arising as a result of the aspiration of oropharyngeal contents [79]. A lateral chest radiograph helps to localize the abnormalities, which are typically subpleural in one of the dependent segments. When aspiration has occurred with the patient lying supine, the apical (superior) segments of the lower lobes tend to receive the aspirate. On the other hand, if the patient is lying on his or her side then the posterolateral parts of the upper lobe tend to receive the aspirate (see Fig. 15.2). The posterior segment of the right upper lobe is affected most commonly, followed by the apical segment of either lower lobe [6]. Occasionally the radiographic features of a complicating effusion, empyema or pneumothorax may be evident (Chapters 14, 43 & 44).

As a lung abscess heals, first the pneumonic infiltrate resolves and during this process the wall of the abscess cavity typically becomes thinner, diminishing in size until it is no longer detectable. A study of 71 patients with lung abscesses found that 13% of cavities had disappeared in 2 weeks, 44% in 4 weeks, 59% in 6 weeks and 70% within 3 months after treatment with appropriate antibiotics [80]. There is residual chest radiographic shadowing when extensive fibrosis has occurred.

Endoscopic or water-soluble, non-ionic contrast (e.g. lopamidol, Gastromiro) examination of the oesophagus should be undertaken if the patient has dysphagia or other symptoms suggestive of gastro-oesophageal reflux, whereas high-osmolality contrast media such as Gastrografin are avoided as spill-over may result in pulmonary oedema.

## Other imaging techniques

When the conventional chest radiographic findings are ambiguous, thoracic CT may be very helpful in accurately defining the extent and disposition of both lung abscesses

**Fig. 15.5** Large lung abscess in right mid zone following staphylococcal pneumonia. Pneumonic changes can be seen below the lesion and also in the left lower zone.

and empyemas [81]. Multiple small air cavities may be clearly demonstrated by CT in necrotizing pneumonia [82]. Fluoroscopy, ultrasound or CT may also be helpful in guiding percutaneous diagnostic thin-needle aspiration of lung abscesses (see below). Although radioactive indium [ $^{111}\text{In}$ ]-labelled leucocytes are taken up in lung abscesses [83], positive results may be produced by other unrelated intrapulmonary pathology so that the investigation has no advantage over conventional radiography.

### Microbiological sampling

#### Blood

Blood cultures should be taken, as pathogens are occasionally isolated in cases of blood-borne (or 'metastatic') lung abscess or when the abscess has complicated pneumonia. Positive blood cultures are unusual in anaerobic infection. Serology may sometimes be helpful, for example when hydatid disease or amoebiasis are considered in the differential diagnosis.

#### Sputum

Sputum examination and culture is also routine as aerobic pathogens may be isolated. There is no point in culturing sputum anaerobically because of inevitable oropharyn-

geal contamination. A clue to anaerobic infection may be the finding in mucopurulent sputum of large numbers of neutrophils with a mixture of many different morphological forms of Gram-positive cocci and Gram-negative rods or fusiform bacilli, the subsequent culture yielding only mixed aerobic respiratory organisms [1,84]. The isolation of aerobes from sputum also has to be treated with some caution because of the same problem of oropharyngeal commensal contamination, although the repeated isolation of a predominant organism suggests that this may be a true pathogen. House staff need to be reminded to specifically request stains and cultures for acid-fast bacilli and fungi in appropriate cases, otherwise these are often not done.

Gas-liquid chromatography has been described as a rapid method for the identification of anaerobes in expectorated sputum, producing a result in under 1 h [85]. It has been claimed that laboratories possessing this facility should be able to use it reliably to distinguish between lower respiratory tract infection and oropharyngeal commensal contamination, the former giving a much stronger response than the latter [86]. The technique detects the presence of the volatile fatty acids that anaerobes produce and that account for the putrid smell associated with this type of infection. No false positives were recorded in one study that made use of this methodology but the equipment is expensive and not widely used [86].

### Other methods

Other methods have been used to obtain specimens uncontaminated by oropharyngeal commensals for the purpose of anaerobic culture. These include percutaneous transtracheal aspiration [87,88], percutaneous needle aspiration of a lung abscess under fluoroscopic or CT control, and bronchoscopic sampling using the fiberoptic instrument and a brush designed to be protected from contamination by oropharyngeal flora [89] (see Chapter 8).

The value of transtracheal aspiration is based on the observation that the trachea is sterile in normal individuals. The procedure requires a cooperative patient and should not be carried out in the presence of hypoxaemia or a bleeding tendency. Although it has been shown to be helpful in diagnosing anaerobic lung infections in research institutions, few practicing physicians in the wider world have mastered the technique, which is now seldom used [27,87,90].

Percutaneous needle aspiration may be used to obtain pus from an abscess of sufficient size to be visible fluoroscopically so that a fine needle can be guided into the lesion under direct vision. The procedure may also be carried out under ultrasound or CT guidance [91,92]. Any air bubbles are expelled from the syringe, which is then sealed and transported directly to the microbiology laboratory. A high diagnostic yield (82%) may be obtained in experienced hands and may lead to changes in antimicrobial therapy [93]. This technique has been compared very favourably with transtracheal aspiration in the diagnosis of anaerobic lung abscess [94]. The prerequisite technical skills are more likely to be provided by an invasive radiologist than by a respiratory physician although, as with transtracheal aspiration, percutaneous needle aspiration of lung abscesses is infrequently carried out in practice, most clinicians basing their choice of antimicrobial therapy on empiricism.

'Protected brushing' via the bronchoscope has been described as a method for obtaining lower respiratory tract secretions that have not been contaminated by oropharyngeal flora [89]. The success of the technique is somewhat limited by the antibacterial properties of lidocaine (lignocaine) so that, ideally, limited quantities of preservative-free local anaesthetic should be used. The temptation to pass a fiberoptic bronchoscopic brush into a large lung abscess should be resisted as this action can precipitate a great flood of pus that may overwhelm a small suction channel and threaten to compromise the patient [95]. Quantitative cultures of bronchoscopic brushings or aspirates have also been proposed, a yield of greater than  $10^3$  colony forming units [cfu]/mL being taken to indicate infection rather than colonization [96,97].

Anaerobes show some degree of susceptibility to the many antimicrobial agents used to treat lower respiratory infection and this adds to the difficulty of isolating them. It

is stressed that close cooperation with the microbiologist is essential when the presence of fastidious organisms such as anaerobes is suspected, in order that specimens are retrieved under optimal conditions and dealt with by the laboratory appropriately and without delay.

### Bronchoscopy

As well as providing a possible method of microbiological sampling (see above), bronchoscopy is diagnostically important when the differential diagnosis includes cavitating lung cancer and when it is necessary to exclude an obstructive proximal lesion such as a bronchial tumour or, less commonly, to identify and remove a foreign body.

## Differential diagnosis

### Cavitating lung cancer

Although lung cancer (usually squamous cell) is a more common cause of a cavitating lung opacity than lung abscess in males over the age of 50 years in the UK, there is usually little difficulty in making a distinction between the two. Patients with a bronchial tumour have no history suggestive of aspiration, and the lesion need not be situated in a typically dependent segment of the lung (see p. 464). A fever, systemic complaints, purulent sputum and leucocyte count greater than  $11.0 \times 10^9/L$  are more likely to be found in the presence of an abscess, as is a response to antibiotic treatment [98]. A chest radiograph showing an eccentric cavity with thick irregular walls may favour the diagnosis of malignant disease but it is unwise to place too much reliance on these features (Fig. 15.6). The cytological examination of sputum or of bronchial aspirates obtained through the fiberoptic bronchoscope may be helpful and any material obtained by percutaneous needle aspiration (see above) should be submitted for cytology as well as microbiological staining and culture.

Lung cancer and lung abscess may occur together, particularly in elderly patients, since necrotic tissue in a tumour may become infected, as well as the tumour itself causing the stagnation of distal secretions with subsequent infection. Where there is persisting doubt about whether the lesion is an abscess or a carcinoma, thoracotomy and removal of the lesion with the surrounding lobe of lung may need to be undertaken, provided that the patient is otherwise fit (see below). Other intrathoracic malignancies, including lung metastases and lymphoma, may also cavitate [99].

### Localized empyema

It may be difficult to distinguish radiographically between a localized empyema with a bronchopleural fistula and a

**Fig. 15.6** Cavitating squamous carcinoma in the right lower zone. Note thick irregular wall and absence of any surrounding pneumonic change.

lung abscess. Classically the empyema is seen on the lateral chest radiograph as a 'D-shaped' opacity, with the convexity projecting anteriorly from the posterior chest wall (see Fig. 14.4). CT may be helpful in doubtful cases, showing an abscess wall of varying thickness with an irregular intraluminal margin and exterior surfaces, whereas the walls of empyema cavities tend to be smooth, separating the thickened pleural layers with compressed lung beneath the visceral layer.

#### **Infected bulla containing a fluid level**

The patient is less ill than might be suggested by the chest radiograph. There may be little evidence of consolidation in surrounding lung when compared with an abscess. The margin of the bulla can often be seen to have a thin, smooth wall on plain films or CT [100] (Fig. 15.7). An earlier chest radiograph may assist in making this diagnosis. Infection within a bulla may cause its obliteration but this is rare [101].

#### **Infected congenital pulmonary lesions**

Bronchogenic and other congenital foregut cysts may be impossible to differentiate from a lung abscess unless previous films are available for comparison. Similar difficulties may be posed by infection in a congenital sequestered segment. The diagnosis is made by the posi-

tion of the lesion (usually lower lobe) and by retrograde aortography. The diagnosis and management of congenital lesions is discussed in Chapter 50.

#### **Pulmonary haematoma**

A history of recent trauma to the chest suggests the diagnosis. Sputum, if present, is not purulent and spontaneous dissolution of the haematoma usually occurs within a few weeks.

#### **Cavitated pneumoconiotic lesions**

Large, well-defined, rounded lesions that may cavitate sometimes develop in coal-workers whose serum is positive for rheumatoid factor, whether or not arthritis is present. The patient gives a history of occupational exposure and need not be ill. Progressive massive fibrosis in coal-miners and silicotic patients may also cavitate (see Chapter 54).

#### **Hiatus hernia**

The diagnosis is suggested by a 'double cardiac shadow' on the posteroanterior chest radiograph and confirmed on the lateral view by the typical appearance of a gastric air bubble behind the heart, often with a fluid level (Fig. 15.8). Further diagnostic confirmation may be provided by a

**Fig. 15.7** (a) Multiple fluid levels on the chest radiograph of a 67-year-old woman with infected cysts or bullae who presented as an outpatient with recurrent cough productive of purulent sputum. She remained symptom-free between infrequent exacerbations. (b) CT of the same patient demonstrating the cysts or bullae after expectoration of their contents.

barium meal or upper gastrointestinal endoscopy if there is doubt.

### **Tuberculous, fungal and actinomycotic infection**

As indicated above, lung abscesses are not all caused by the usual anaerobic and aerobic bacteria and acid-fast bacilli, fungi and *Actinomyces* may also cause pulmonary suppuration (Chapters 17 & 21). Chronic cavitary histoplasmosis may simulate tuberculosis radiographically, as may rhodococcal infection in immunosuppressed patients

and melioidosis (caused by *Ps. pseudomallei*) in patients from endemic areas [71].

### **Hydatid cysts and other lung parasites**

Hydatid cysts may rupture and develop bacterial superinfection [102]. The diagnosis should be suspected in people who have lived in sheep-farming areas. In such cases aspiration should not be attempted as this is likely to disseminate the disease. Latex agglutination, complement fixation and enzyme-linked immunosorbent assay are available for detecting antibodies in the serum (Chapter 22). Paragonimiasis (*Paragonimus westermani*, the lung fluke) may also simulate lung abscess and is endemic in parts of West Africa, the Indian subcontinent, the Far East and Central and South America [103].

### **Other conditions**

Other conditions that can be confused with lung abscess include cavitating pulmonary infarcts and Wegener's granulomatosis [16,104,105]. Sarcoidosis may rarely cavitate [106]. Massive pulmonary gangrene is a rare complication of pneumonia and can result in cavitation [107].

## **Treatment**

### **Antibiotics**

Antibiotic therapy has been the mainstay of treatment in lung abscess for over 40 years. Penicillin has retained its prominence throughout this period and has only recently fallen back slightly from the vanguard, largely as a result of the emergence of strains of  $\beta$ -lactamase-producing Gram-negative anaerobic bacilli. Nearly all lung abscesses form early communications with the tracheobronchial tree, hence the appearance of fluid levels. Their contents can therefore be coughed up and with the ready availability of antibiotics it is now unusual for operative surgical treatment to be required, about 90% of patients with anaerobic (putrid) lung abscess responding to medical treatment [108].

As mentioned above, there are inherent difficulties and inevitable delays in obtaining reliable microbiological information in cases of lung abscess so that, as with pneumonia, the clinician is usually obliged to adopt an empirical approach to therapy, basing the choice of antibiotic on probability. The majority of lung abscesses are related to aspiration and are caused by anaerobes; thus a history and clinical findings consistent with community-acquired lower respiratory tract infection followed by a localized area of abscess formation suggests that these organisms are very likely to be the culprits and treatment may be tailored accordingly. When, as is less usual, a lung abscess is thought to have been acquired during a period in hospital,

**Fig. 15.8** (a, b) Posteroanterior and lateral radiographs showing enormous hiatus hernia extending beyond both sides of the cardiac contour. (c) In addition to the usual gastric findings, CT demonstrated that the right paracardiac opacity contained omentum and large bowel. The hernia was surgically repaired.

the range of antibiotics may need to be broadened in order to cover not only anaerobes but also the wider spectrum of organisms that tend to colonize the pharynx in sick hospitalized patients and lend themselves to aspiration. These include genera within the family Enterobacteriaceae, such as *Klebsiella*, *Proteus*, *Serratia*, *Enterobacter* and *E. coli*, as well as other pathogens such as *Ps. aeruginosa*, *Acetivobacter* species and *Staph. aureus* (see Chapter 13).

#### **Benzylpenicillin, clindamycin and metronidazole**

Although most anaerobes remain sensitive to benzylpenicillin (penicillin G), increasing numbers of strains are becoming resistant. These include the  $\beta$ -lactamase-producing Gram-negative organisms previously known as *B. melaninogenicus* (now assigned to the genera

*Prevotella* and *Porphyromonas*), members of the *B. fragilis* group and some strains of *Fusobacterium*.

Although benzylpenicillin as a single agent may still be effective, particularly in less severe infections, concerns about resistance led to two prospective randomized trials in the 1980s in which penicillin was compared with clindamycin. This drug is active against *B. fragilis* and other penicillin-resistant anaerobes, as well as having some activity against *Staph. aureus* [109,110]. Both of these studies showed that clindamycin had the edge over penicillin in terms of lysis of fever and clearing of sputum, with fewer treatment failures and relapses. Although potentially more toxic, clindamycin may therefore be used as a substitute for penicillin and is certainly a rational choice in a patient who is allergic to penicillin. Its most serious limiting side-effect is pseudomembranous colitis. Another

approach has been to add metronidazole to penicillin as a second supporting antibiotic in all but the mildest infections [26,111]. Metronidazole is a suitable choice as it is active against all Gram-negative anaerobes, including *B. fragilis* (which is resistant to penicillin but sensitive to clindamycin) as well as *Clostridium* species. It is *not* standard practice to use metronidazole alone, as some anaerobic cocci and most microaerophilic streptococci (e.g. *Strep. milleri/intermedius*) are resistant to it, which may lead to a significant number of treatment failures if the drug is used singly, whereas these organisms will be dealt with by the addition of penicillin [112].

Dosage depends on the severity of the infection. In the case of benzylpenicillin, high doses are recommended [113]. A daily regimen using 6–12 g (5–10 megaunits) intravenously is usually appropriate, although doses of up to 24 g (20 megaunits) can be used. It is appropriate to supplement this with metronidazole 500 mg intravenously every 8 h by infusion. Modifications to treatment may be made according to response or in the light of culture and sensitivity results. As infection comes under control it is possible to reduce the dose of penicillin, switching to an oral form such as phenoxymethylpenicillin (penicillin V) 0.5–1 g every 6 h and to give the metronidazole, which is very well absorbed, in standard oral dose (400 mg every 8 h). The dose of clindamycin is 600 mg intravenously every 6–8 h, switching to oral therapy at a dose of 300 mg every 6–8 h.

### Other antibiotics

Many other antimicrobial agents are active against anaerobes *in vitro* but have not been subjected to clinical trials in patients with lung abscess, largely because of the relative infrequency of this type of sepsis and because of the fastidious nature of trial-regulating agencies who require microbiological proof of the responsible organisms. These apparently effective antibiotics include most but not all  $\beta$ -lactams, activity being particularly augmented by combination with a  $\beta$ -lactamase inhibitor, as in the case of amoxicillin and clavulanic acid (co-amoxiclav). Similarly, in the USA, ampicillin is available in combination with the  $\beta$ -lactam inhibitor sulbactam.

Other penicillins with activity against anaerobes include the extended-spectrum (antipseudomonal) penicillins, such as the ureidopenicillins piperacillin and azlocillin and the carboxypenicillin ticarcillin, which may be appropriate when the infection has been acquired in hospital, in which case a mixed flora with Gram-negative aerobes as well as anaerobes is more likely to be encountered. Ticarcillin is also commercially available combined with the  $\beta$ -lactamase inhibitor clavulanic acid as ticarcillin–clavulanate, and piperacillin has been combined with the  $\beta$ -lactamase inhibitor tazobactam as piperacillin–tazobactam.

Imipenem, which is a carbapenem  $\beta$ -lactam, has excellent *in vitro* activity against anaerobes, as well as activity against a wide spectrum of Gram-positive and Gram-negative bacteria, including *Ps. aeruginosa*.

Of the cephalosporins, cefoxitin (considered 'second generation' but in fact a cephamycin) is the most potent *in vitro* against the *B. fragilis* group, tending to be relatively resistant to  $\beta$ -lactamases produced by Gram-negative bacilli. Third-generation cephalosporins, for example ceftazidime, and related drugs are less active against anaerobes and better avoided in this clinical setting.

Chloramphenicol is very effective *in vitro* against virtually all anaerobes but, because of its potential for marrow suppression, tends only to be used in life-threatening situations when other therapy is judged to be failing or is unavailable.

The macrolides (e.g. erythromycin, clarithromycin and azithromycin) are not ideal as single agents as they have poor activity against anaerobic fusobacteria, although this can be offset by combining them with metronidazole.

Tetracyclines are best avoided as significant numbers of resistant anaerobic strains have emerged. Quinolones as a group are also relatively ineffective against anaerobes. Of the other  $\beta$ -lactam antibiotics, aztreonam is ineffective. So are co-trimoxazole (trimethoprim–sulfamethoxazole) and the aminoglycosides, although the latter may be considered as part of a combination regimen to cover Gram-negative aerobic bacilli.

Multiple lung abscesses or septic infarcts occurring in association with staphylococcal bacteraemia ordinarily respond to flucloxacillin or other antistaphylococcal penicillins, whereas vancomycin or teicoplanin (see Chapter 9) tend to be effective in pulmonary sepsis due to methicillin-resistant *Staph. aureus* [114].

The optimum route and duration of treatment in lung abscess have not been determined but it is common practice to give antibiotics intravenously initially as above, converting to oral therapy when a favourable response has become plainly evident. The pyrexia usually settles more gradually than is the case in non-suppurative pneumonia and may take 7 days or more to return to normal. A reappraisal of the treatment regimen is reasonable if the pyrexia has not begun to settle after 1 week [1]. Radiographic improvement also tends to be slow, commonly extending over weeks and there may be some residual fibrosis. It is usual to treat for 4–6 weeks and this may sometimes need to be extended for up to 3 months in order to achieve cure and prevent relapse. The point of discontinuance is impossible to define precisely, being determined empirically by the patient's clinical state and by a satisfactory radiographic improvement with the chest radiograph showing either complete clearing or a stable residual area of fibrosis.

## Physiotherapy

Physiotherapy may be useful in helping the patient to clear purulent material, the site of the abscess having been determined radiographically, so that postural drainage can be applied with the affected pulmonary segments uppermost.

## Bronchoscopy

Bronchoscopic drainage of lung abscesses using cardiac catheters has been described [115,116]. However, this technique is seldom used and it should be remembered that on rare occasions pus from a large abscess may flood into the tracheobronchial tree, so that rigid bronchoscopy is probably safer as it allows adequate suctioning [95]. As previously mentioned, the main role of bronchoscopy in lung abscess is diagnostic.

## Surgery

Surgical management is rarely required in countries where early and effective antibiotic treatment is available [108,117]. Such treatment was reviewed by Le Roux [118] whose South African practice afforded him considerable exposure to cases of pleuropulmonary sepsis.

These approaches include intercostal catheter or tube drainage to an underwater seal bottle [119,120]. Such intervention carries the risk of haemorrhage, pneumothorax, bronchopleural fistula and empyema, although a number of reports in the literature indicate that these complications are infrequent and that these procedures are usually effective where medical treatment has failed [7]. Modern interventional radiography has made it possible for experienced hands to place small catheters with considerable accuracy [121].

Open drainage via pneumonostomy is even less frequently carried out, the drain being removed within 48 h

of insertion as the cavity tends to close more rapidly than in empyema, in which longer periods of drainage are required.

Surgeons may resort to resective surgery if antimicrobial treatment fails and if external drainage has also been ineffective but this too is rarely required. In modern practice any form of surgical intervention, other than bronchoscopy, is required in less than 10% of patients with lung abscess, although in occasional cases medical treatment with antimicrobial agents may serve only to convert a subacute abscess into a more chronic one, so that serious and protracted symptoms result from the presence of an area of grumbling sepsis surrounded by extensively damaged and functionless lung. In this situation thoracotomy and lung resection (usually lobectomy) may have to be carried out. However, the most frequent indication for thoracotomy and resection is the suspicion that the abscess is a cavitating tumour or that it has occurred in close association with a carcinoma that cannot be convincingly excluded by other means. Lung resection is also occasionally necessary for massive and life-threatening haemoptysis. This alarming event may require emergency rigid bronchoscopy. Suction is applied to rid the contralateral lung of blood so that the patient is prevented from drowning. The situation may be improved by bronchoscopic tamponade with gauze swabs, by the placement of a balloon catheter in the bleeding bronchus or preferably by the use of a double-lumen endotracheal tube. Such large bleeds may be preceded by smaller haemoptyses. Bronchoscopy may be usefully carried out at this stage in order to identify the bleeding bronchus for future reference should a large bleed occur. Fortunately such massive haemoptyses are rare [117].

In a surgical series of 89 patients collected between 1968 and 1982 only 9% came to resective surgery and in all but two of these surgery was performed because carcinoma was suspected [77]. Hagan and Hardy [117] recorded resections in 10% of 184 cases between 1980 and 1982.

# TUBERCULOSIS: PATHOGENESIS, EPIDEMIOLOGY AND PREVENTION

A. GORDON LEITCH

Tuberculosis is a disease of great antiquity. What were almost certainly tuberculous lesions have been found in the vertebrae of neolithic man in Europe and on Egyptian mummies dating possibly from as early as 3700 BC [1]. Today, tuberculosis has become the most important communicable disease in the world, with over 8 million cases of pulmonary tuberculosis occurring each year, 95% of which are in developing countries [2–4]. The World Health Organization (WHO) estimates that the annual number of new cases of tuberculosis will increase to 10 million by 2000 and that deaths attributable to tuberculosis will rise from 2.5 million to 3.5 million by the end of the millennium [5]. The advent of human immunodeficiency virus (HIV) infection has had a substantial impact on the incidence of tuberculosis, particularly in developing countries [6], and is compounded by the inadequate provision of, and access to, services in these countries [5]. Nor is tuberculosis unknown in the economically developed world: in 1991 in New York City, 3673 cases were reported, representing an increase of 143% over the incidence in 1980 [7]. This increase in tuberculosis cases in New York was largely attributed to the decline of tuberculosis control programmes [8] and their reinstitution led to a fall in annual notified cases to 3235 in 1993 [9], but not before the rates in central Haarlem (>150 cases per 10000 population) had equalled those in some parts of sub-Saharan Africa [10]. The New York experience is an extreme example of the consequences of assuming that a previously established annual decline in notifications of tuberculosis will continue. As tuberculosis has declined in the developed world there has been an associated decrease in experience and awareness of the disease, as reflected by increasing numbers of diagnoses of tuberculosis made after, rather than before, death [11–15]. Even in teaching hospitals delays in diagnosis due to failure to suspect the disease are not uncommon [15]. As tuberculosis has been a curable disease since the principles of chemotherapy were established almost 40 years ago [16,17], such a situation is to be deplored and the author makes no apologies for considering the subject in some detail. This chapter is concerned

with the pathogenesis of the disease, its epidemiology and methods of control and prevention.

## Pathogenesis

### Tubercle bacillus

Koch first described the tubercle bacillus now known as *Mycobacterium tuberculosis* in 1882 [18]. Mycobacteria are now known to comprise a large group of acid-fast, alcohol-fast, aerobic or microaerophilic, non-spore-forming, non-motile bacilli [19]. Of the many different mycobacteria, only *M. tuberculosis*, *M. bovis* and *M. africanum* are recognized as tubercle bacilli, these all being subspecies of a single species. *M. tuberculosis* is an obligate parasite that is infectious to humans, other primates and to many other mammals. It produces progressive tuberculous disease in guinea-pigs.

Tubercle bacilli are difficult to stain but once stained they strongly retain the dye, which is not removed by acid-alcohol solution. This acid and alcohol fastness can be demonstrated by the Ziehl–Nielsen staining procedure, of which there are various modifications (Fig. 16.1a). Tubercle bacilli can also be stained by fluorescent dyes, such as auramine and rhodamine, and acid-fast staining procedures have been developed with these fluorescent dyes in which the bacilli fluoresce strongly (Fig. 16.1b).

In culture tubercle bacilli grow slowly, taking 2–6 weeks to form colonies on egg (e.g. Lowenstein–Jensen medium) and oleic acid–albumin agar media. Growth is optimal at temperatures of 33–39°C at pH 6.5–6.8 in an atmosphere of 5–10% CO<sub>2</sub>. Identification tests include production of niacin, of which *M. tuberculosis* produces the most. Supportive tests for *M. tuberculosis* include strongly positive nitrate reduction and loss of catalase activity at 68°C. *M. bovis* is weak on nitrate reduction and is a low niacin producer; in general *M. africanum* appears to be intermediate in characteristics between *M. tuberculosis* and *M. bovis*, although some have questioned the validity of this subspecies [20].

**Fig. 16.1** (a) Ziehl–Nielsen stain of sputum: acid-fast bacilli stain purplish pink ( $\times 1000$ ). (b) Fluorescent (auramine–phenol) stain of same specimen showing massive numbers of tubercle bacilli ( $\times 400$ ).

In stained smears of pathological material, *M. tuberculosis* is seen as slightly bent rods, 2–4  $\mu\text{m}$  long and 0.2–0.5  $\mu\text{m}$  wide, which may be evenly stained or beaded and granular. On solid or liquid media the bacteria tend to be parallel and form long threads or cords.

It is important to recognize that all three mycobacteria cause disease in humans that is histopathologically and clinically indistinguishable.

### Transmission

For many years tuberculosis was thought to be transmitted genetically. Even today, patients who have little or no idea of the theory of infection may express surprise when informed of the diagnosis of tuberculosis because 'it's not in my family, doctor'. Even before the tubercle bacillus was described, there were those who had their suspicions about the mode of transmission. In 1856, the English epidemiologist William Budd wrote: 'Everywhere along the African seaboard, where the blacks have come into contact and intimate relations with the whites, phthisis causes a

large mortality among them. In the interior, where intercourse with Europeans has been limited to casual contact . . . there is reason to believe that phthisis does not exist' [21]. It is now known that infection is transmitted by the airborne route and that the unit of infection is a small particle called a droplet nucleus.

The importance of the size of the infecting particle was first shown by Wells *et al.* [22]. Rabbits inhaling two or three bovine tubercle bacilli dispersed as single units contracted more pulmonary tuberculosis than those inhaling 10000 bacilli dispersed in large aggregates. The smaller particles were deposited on the alveolar surface, whereas the larger particles impacted in large airways and were cleared by mucociliary transport mechanisms. In small mammals it has been shown that almost all tubercle bacilli inhaled as single organisms reach an alveolus and produce a tubercle and that it is unusual for more than a single organism to be deposited at any one site [23,24]. It was postulated that airborne tuberculosis develops in humans by inhalation of a single bacillus contained in a droplet nucleus.

Coughing, spitting, sneezing, singing and other respiratory manoeuvres generate droplet nuclei due to evaporation of small respiratory droplets. These droplet nuclei are dispersed throughout space without settling and the organisms that they contain can remain viable for extended periods of time [25]. They are not filtered by simple gauze masks nor prevented from entering room air by covering the mouth and nose during coughing. Outdoors, organisms in droplet nuclei are eliminated by infinite dilution and by radiation from the sun.

In an elegant experiment reported by Riley *et al.* [26], the contribution of droplet nuclei to transmission of infection from smear-positive patients was investigated. A six-bedded research ward occupied by a succession of smear-positive patients had its air vented through exhaust ducts past guinea-pig colonies housed in exposure chambers in a penthouse on the roof of the hospital. All guinea-pigs were tuberculin tested at monthly intervals and positive reactors sacrificed and replaced by uninfected animals. In the first year of the study, of the 135 guinea-pigs that were exposed an average of approximately three per month became infected. The characteristic lesion was the single pulmonary tubercle with hilar node and spleen involvement. Control animals exposed to ward air disinfected with ultraviolet light did not become infected. In most instances the drug-susceptibility patterns of bacilli from infected guinea-pigs could be matched against similar organisms in the sputum of a patient in the ward at the time the animal was infected.

From this experiment, knowing the number of infectious particles (number of infected guinea-pigs) and the volume of air in the exhaust, it was possible to estimate the concentration of infectious particles in the air. Hence, ward air was calculated to contain one infectious particle per 340 m<sup>3</sup>. It would take a nurse in such a ward about 1 year on average to inhale one infectious particle, an observation consistent with epidemiological data on the time of tuberculin conversion in nurses working on such wards in the era before chemotherapy [27].

Another example that emphasizes the importance of droplet transmission compares with spread by direct contact is seen in the outbreak of tuberculosis aboard the naval vessel *Richard E. Byrd* [28], which carried a single smear-positive tuberculous crewman. The air in the interior of the ship was recirculated and the ventilation systems serving two large bunking compartments were interconnected. Occupants of the two compartments had very little contact with each other at any time. Nevertheless, the rate of infection with tuberculosis in crewmen who had no contact with the smear-positive index case was the same as in those who had direct contact because they shared the same compartment.

These reports emphasize the importance of droplet nuclei in the transmission of tuberculosis. Riley's study confirms that, in general, prolonged contact with a highly

infectious case is necessary before infection is acquired. At the other extreme, infection may be acquired by a single exposure, for example in laboratories or postmortem rooms [29]. Hospital staff exposed to patients with tuberculosis (even smear-negative tuberculosis) undergoing intubation, assisted ventilation and fiberoptic bronchoscopy have shown a high rate of tuberculin conversion [30]. Transmission to and from the HIV-infected patient is more likely [31], particularly where cough-inducing procedures such as sputum induction or pentamidine nebulization are being employed, and recommended precautions should be taken [32,33].

A number of factors, apart from smear positivity, may influence the infectivity of a particular patient. A bout of coughing produces up to 3500 droplet nuclei, a number that equates with speaking for 5 min in a normal tone. Loudon and Roberts [34,35] compared patients' nocturnal cough frequency recorded on tape with the percentage of their household contacts infected. Patients who coughed more than 48 times per night infected 48% of their contacts, while patients who coughed less than 12 times per night infected only 28% of their contacts. Duration of coughing prior to diagnosis is also clearly important. In one study 84% of patients had been coughing for 3–6 months [36]. The physical and chemical characteristics of the sputum may also influence infectivity. Guinea-pigs exposed to artificially atomized standard doses of different infected sputum samples show a marked variation in degree of infection [37]. Tenacious sputum may be more infectious than watery sputum. Finally, sputum from patients on effective chemotherapy is much less infectious, as shown by the low rate of infection of the penthouse guinea-pigs breathing air from the tuberculosis ward containing such patients [26]. This would accord with studies from Baltimore [38], Madras [39] and expert opinion [40] that most, if not all, contacts of patients with tuberculosis are infected prior to the initiation of effective chemotherapy. Most physicians now consider, on the basis of these findings, that after 1 or 2 weeks of effective chemotherapy the risk of transmission of tuberculosis is minimal, even from a smear-positive patient.

### Prevention of transmission in hospitals

From the point of view of hospital practice, the 1967 recommendations of the National Tuberculosis Association [41] have now been complemented by advice from the American Centers for Disease Control [42] and the British Thoracic Society [33] as well as from the International Union Against Tuberculosis and Lung Disease and the Tuberculosis Programme of the WHO [43]. These authorities accept the droplet nucleus mechanism of transmission and rely principally on chemotherapy to prevent transmission of disease. Isolation of patients suspected of having tuberculosis who are hospitalized is recommended

until three sputum smears are known to be negative for *M. tuberculosis* and the patient therefore non-infectious. Immunosuppressed patients (e.g. those with AIDS) should not be admitted to a tuberculosis ward until tuberculosis is confirmed and treatment has begun.

Patients with sputum smear-positive pulmonary tuberculosis, i.e. those who are infectious, should ideally be isolated from all other non-tuberculous patients until they have negative sputum smears and certainly until they have been treated for 2 weeks. Patients with HIV infection and tuberculosis or those in whom infection with drug-resistant organisms is suspected should be isolated until sputum is negative for acid-fast bacilli. Healthcare staff need to be educated about tuberculosis and those who are known to be HIV positive should not work with tuberculous patients.

Isolation rooms should be well ventilated to the outside and special precautions are required during cough-inducing procedures. Infectious patients who are being transported to other areas of the hospital should wear tight-fitting masks that filter particles 1–5 µm in diameter. Surgical masks may prevent dissemination from coughing patients but do not protect staff from inhalation of droplet nuclei. Following the occurrence of outbreaks of multidrug-resistant tuberculosis in the USA, the introduction of high-efficiency particulate air filter respirators was recommended; an analysis from Virginia, USA showed that, in one hospital, this intervention would only prevent one case of occupationally acquired tuberculosis at a cost of \$US1.3–18.5 million [44]. Such highly efficient interventions are not generally required.

## Pathology

Deposition of tubercle bacilli in the alveoli of the lungs is followed by vasodilation and an influx of polymorphonuclear leucocytes and macrophages to the area. After several weeks the polymorph numbers diminish and macrophages predominate. The macrophages develop pale foamy cytoplasm rich in lipid and crowd together as epithelioid cells to form the tubercle or unit lesion of tuberculosis (Fig. 16.2). Some mononuclear cells fuse to form the multinucleated or Langhans' giant cell. Lymphocytes surround the outer margin of the tubercle and in the centre of the lesion a zone of caseous necrosis may appear that may subsequently calcify.

Primary infection is usually evident as a subpleural tubercle (the primary or Ghon focus), which may be in any lung zone and which drains via lymphatics to hilar lymph nodes to form the primary complex. Most primary infections heal with or without calcification of the primary complex, although haematogenous spread probably occurs via the lymphatics in the majority of infected subjects, resulting in the seeding of tubercle bacilli to other parts of the lung as well as other organs [45]. Studies with

radioactive bacille Calmette–Guérin (BCG) suggest that within an hour of the bacilli reaching the lung they reach the lymph glands and often the bloodstream [46].

The infection is usually contained at extrapulmonary sites, as it is in the lung, but the potential for reactivation of infection at all sites is always present. The primary lesion sometimes progresses and the pathological changes are then similar to those seen in reactivation tuberculosis. Reactivated pulmonary tuberculosis is most often seen in the upper lung zones and is limited in extent, most frequently to the posterior segment of the upper lobe or the apex of the lower lobe. The high ventilation–perfusion ratios, with alveolar  $PO_2$  elevated relative to other zones, is believed to predispose to reactivation at these sites [45]. Proliferation of tubercle bacilli in the caseous centres is followed by softening and liquefaction of the caseous material, which may discharge into a bronchus with resultant cavity formation. Whereas  $10^4$  bacilli per gram are found in caseous tissue, up to  $10^9$  organisms may be harboured within a single cavitary lesion [47]. Fibrous tissue forms around the periphery of such tuberculous lesions but is usually incapable of limiting extension of the tuberculous process. Haemorrhage may result from extension of the caseous process into vessels within the cavity walls. Spread of caseous and liquefied material through the bronchial tree may disseminate the infection to other lung zones with or without the development of a vigorous inflammatory exudate or tuberculous pneumonia.

Rupture of a caseous pulmonary focus into a blood vessel may result in miliary (*milia*, a seed) tuberculosis, with the formation of multiple 0.5–2 mm tuberculous foci in the lung and in other organs of the body. Encroachment on bronchi of pulmonary or lymph node caseous material may give rise to tuberculous bronchitis. Rupture of caseous glands into trachea or major bronchi causes collapse of lung or even sudden death by suffocation in young children.

## Immunology [48]

Koch first described the reinfection phenomenon that still bears his name [49]. Primary infection in guinea-pig skin was associated with a slowly progressive, well-localized, granulomatous response with lymph node involvement. Subsequent infection with the same organism led to the development of an early localized indurated lesion that peaked at 72 h followed by rapid healing. A similar secondary response could be induced in the skin of tuberculous patients by the intradermal injection of heat-killed tubercle bacilli or an extract of this organism (tuberculin). The true nature of this diagnostic reaction was elucidated some 30 years later [50].

A positive skin reaction to tuberculin cannot be transferred to tuberculin-negative recipients by means of hyperimmune serum. It can be transferred to non-infected

**Fig. 16.2** (a) Large caseous granulomatous lesion of tuberculosis showing central necrosis, a surrounding zone of epithelioid cells and giant cells, and a peripheral ring of lymphocytes and fibroblasts (haematoxylin & eosin  $\times 35$ ). (b) Same lesion showing small epithelioid cell granuloma with giant cells (haematoxylin & eosin  $\times 110$ ). (c) Another area of the same lesion showing Langhans-type giant cells and epithelioid cells centrally, necrosis to the left and lymphocytes and fibroblasts to the right (haematoxylin & eosin  $\times 110$ ).

individuals by an infusion of lymphoid cells from tuberculin-hypersensitive donors [51]. In mice the same procedure results in the transfer of antituberculous immunity [52]. Immunity and hypersensitivity are now known to be mediated by a population of immunocompetent T lymphocytes originating in the thymus-dependent areas of the spleen and lymph nodes [53], and in the naturally infected host both hypersensitivity and immunity are believed to develop simultaneously [54].

Lurie [55] was the first to demonstrate in rabbits that the immune or antimycobacterial response of previously infected animals to subsequent mycobacterial challenge was mediated by a population of mononuclear phagocytes that ingested and killed tubercle bacilli at an increased rate compared with normal macrophages. The essentially cellular nature of the antituberculous immune response was subsequently confirmed [56,57], leading to the concept that cell-mediated immunity alone was responsible for this acquired resistance.

The immunity transferred by an initial infection is today utilized in the form of vaccination with BCG. BCG is derived from a virulent strain of *M. bovis* initially attenuated by cultivation on a potato–glycerine–bile medium for 230 serial transfers [58], thus achieving immunogenicity without pathogenicity. BCG confers immunity by activation of macrophages within the reticuloendothelial organs of the immunized host, with resultant limitation of mycobacterial growth on subsequent challenge [59]. The immune host (whether protected by previous infection or BCG) is not protected from subsequent infection [60] but in such a host the rate of growth of *M. tuberculosis* is slowed compared with that seen in non-immunized controls [61].

As already mentioned, acquired immunity is mediated by T cells, almost certainly Th1 cells [62], which reach the tubercle from the spleen and lymph nodes [53]. On contact with antigen processed by macrophages in the tubercle, lymphokines such as interleukin 2 and interferon  $\gamma$  [62] are released and activate blood-derived monocytes entering the lesion. These activated macrophages show structural, enzymatic and metabolic changes [63] and phagocytose and kill tubercle bacilli at a markedly enhanced rate compared with unstimulated cells. The central role of T cells in mediating this antituberculous response can be seen in the inability of T cell-depleted mice to develop tuberculin hypersensitivity or resistance to tuberculous infection following challenge with tubercle bacilli [64].

The positive tuberculin skin test is the earliest indicator of infection with tuberculosis [65]. It is not a universal finding in patients with clinical tuberculosis and it is critical to note that a negative tuberculin test does not exclude tuberculosis [66,67]. Numerous reports have documented the occurrence of negative tuberculin tests in patients with tuberculosis, particularly in those with miliary tuberculosis [68], cryptic miliary tuberculosis [69–72] and extensive

disease [73] and in older patients [74,75]. The presence of anergy may be due to the activation of suppressor lymphocytes [76] or the presence of a population of adherent cells, presumably macrophages, with suppressor properties [77,78]. Alternative explanations include defects in lymphokine production and compartmentalization of sensitized lymphocytes [79]. As a rule, tuberculin anergy, whatever its cause, disappears after successful treatment of the underlying disease [66,80,81].

It has been suggested that tuberculosis, like leprosy, is a disease with a wide immune spectrum [82]. Most patients, for example those with tuberculoid leprosy, develop disease characterized by granuloma formation and cellular hypersensitivity documented by a positive tuberculin test. A few patients, for example those with cryptic miliary tuberculosis, present with a pattern of disease akin to lepromatous leprosy where bacillary multiplication is uncontained and skin tests are negative. These patients are anergic, both *in vivo* and *in vitro* (when cultured lymphocytes are stimulated by either antigen or mitogen), and have augmented B-cell antibody-mediated responses [83,84]. Lenzini *et al.* [85] have attempted to correlate the immune with the clinical spectrum of tuberculous disease. Although the extremes of their spectrum (UU, unreactive; RR, reactive tuberculosis) are readily recognizable in the terms described above, their intermediate categories (RI, reactive intermediate; UI, unreactive intermediate) are less convincing on clinical grounds. Nevertheless, the classification draws attention to unreactive disease, which is likely to be increasingly prevalent in developing countries as reactivation occurs in an ageing population.

### Patterns of presentation: the timetable of tuberculosis

Most primary tuberculous infections heal spontaneously and are contained by the body defences described above. There may be no residua visible on the chest film or there may be variable calcification of the primary lesion and complex. In some patients there may be sequelae to the primary tuberculous infection and, in general, these tend to conform to a 'timetable of tuberculosis' (Fig. 16.3). Wallgren [86] described this timetable in Sweden in 1948 in the era before chemotherapy or BCG when the majority of cases of tuberculosis occurred in the young; for example in Scotland in 1949, 50% of pulmonary and 74% of extrapulmonary notifications were aged under 25 years [87]. The timetable is presumably still largely applicable to the high-prevalence countries of the developing world but should be applied with caution to manifestations of tuberculosis in the developed world, for example in Scotland in recent years only 12% of tuberculosis cases were aged less than 25 years and 38% were over 65 years [88]. These elderly cases of tuberculosis probably represent reactivation disease developing many decades removed from the

Tuberculin test becomes positive.  
Minority of those infected experience  
febrile illness and erythema nodosum.

Miliary and meningeal tuberculosis  
common in children under 5 years:  
pleural effusion rare in children.  
Usually within 6–12 months, after  
primary infection.

Adult (post-primary) disease and skeletal  
disease commonly occurs 1–5 years later.

Genito-urinary and skin lesions are  
late manifestations after 5–15 years.

**Fig. 16.3** Natural history of untreated primary tuberculosis: the timetable of tuberculosis. See text for explanation.

primary infection and occur with both pulmonary and non-pulmonary disease [89–91]. These cases, as well as cryptic miliary disease [91], could be described as 'stations further along the line' on Wallgren's timetable [88].

In children especially, enlarged hilar lymph nodes may compress or erode bronchi with resultant lobar consolidation and collapse, a phenomenon formerly called epituberculosis. Miliary tuberculosis and tuberculous meningitis, which was frequently associated with miliary tuberculosis, occurred usually within 6 months of the primary infection and were especially common in children under 5 years. Meningitis is also sometimes a terminal event in cryptic miliary disease in the elderly. Pleural effusion, presumably due to seeding of the pleura from a lung focus, also occurred early, usually within 6–12 months, and was commoner in young adults and unusual in small children. In young adults the primary disease could progress, with increasing infiltration and cavitation evident 1–2 years or even later after the primary infection. This type of disease was labelled progressive primary or postprimary disease and occurred most commonly at puberty. Skeletal tuberculous lesions, most commonly of the spine, could also present 1–5 years after the primary infection. Lesions of the genitourinary tract [92] and the skin made their appearance much later, commonly 5–15 years after the primary infection. The most common type of disease seen in developed countries today, postprimary or reactivation disease of late middle age or the elderly, is due to reactivation of apical pulmonary foci that were seeded at the time of the primary infection, have lain dormant and then present with progressive cavitating pulmonary disease many decades after the initial primary infection. Finally, cryptic miliary tuberculosis or anergic tuberculosis of the elderly is an extreme variant of reactivation tuberculosis that also presents late in life and may be associated with an entirely normal chest radiograph.

Important information is available on the development of clinical tuberculosis following primary infection acquired during adolescence, based on the British Medical Research Council's tuberculosis vaccines trial [93,94]. There were 54239 participants in this trial aged 14–15.5 years on entry in 1950–52. Of the 32282 participants who were tuberculin negative (to 100 tuberculin units, TU) with a normal chest film, 12867 chosen at random were left unvaccinated and were followed by means of periodic tuberculin tests and chest films for about 10 years; cases of tuberculosis developing among them were recorded for a total of 20 years. Taking 8 mm of induration or more to 3 TU as indicative of infection with tuberculosis (a fairly strict criterion), 1335 of the 12867 participants were infected and 108 cases of clinical tuberculosis (or 8.1% of those infected) developed in the 10 years following the primary infection. In total 243 cases of tuberculosis developed among all the initially tuberculin-negative partici-

pants within 15 years of entry [93]. Of these 243 cases, 54% had developed disease within 1 year and 80% within 2 years of infection as shown below [94]:

First year, 54%

Second year, 24%

Third year, 9%

Fourth year, 5%

Fifth and sixth years, 3%

Seventh and eighth years, 3%

Ninth year and above, 1%.

The greatest risk of disease following primary infection was therefore within the first 2 years. The nature of disease in those with clinical tuberculosis is shown in Table 16.1. The striking feature is the high incidence of cavitary disease in these progressive primary lesions. The high incidence of pleural effusion and low incidence of non-pulmonary tuberculosis are also of interest. Further analysis of these data [94] demonstrated the interval from infection to onset of disease for the different forms of the disease (Table 16.2). These findings are in keeping with Wallgren's timetable [86], with more miliary tuberculosis or meningitis occurring in the first year than the pulmonary forms of the disease and relatively less of the other non-pulmonary tuberculosis occurring in the first year. With tuberculosis, as with any other disease, there are of course no absolute rules of behaviour, but these figures illustrate in general terms much of what was known about the natural history of the disease before specific interventions were applied.

## Epidemiology

Keeping track of tuberculosis is not easy but not impossible. Historically, death rates from tuberculosis were the obvious indicators; however, at present, mortality from tuberculosis is less common in developed countries and though common in developing countries is poorly recorded. In both situations the mortality rate from

**Table 16.1** Nature of disease developing in the 243 initially tuberculin-negative patients followed for 15 years in the British Medical Research Council vaccines trial. (From Medical Research Council [93] and Sutherland [94].)

	No.
Tuberculous meningitis	5 (2%)
Pulmonary tuberculosis	
Miliary	5 (2%)
Non-miliary with cavitation	52 (21%)
Non-miliary without cavitation, extensive lesions	11 (5%)
Non-miliary without cavitation, less extensive	100 (41%)
Pleural effusion	51 (21%)
Non-pulmonary tuberculosis	19 (8%)

	Total no.	Cases in first year	
		No.	Percentage
Miliary tuberculosis, meningitis	10	7	70
Pleural effusion	51	28	55
Pulmonary tuberculosis: no cavitation	111	59	53
Pulmonary tuberculosis: cavitation	52	30	58
Non-pulmonary	19	8	42
Total		132	54

**Table 16.2** Form and timing of disease onset in the 243 cases of tuberculosis reported in the British Medical Research Council vaccines trial. (From Medical Research Council [93] and Sutherland [94].)

**Fig. 16.4** Death rates for respiratory tuberculosis in Scotland and in England and Wales 1900–85.

tuberculosis is not the appropriate parameter by which to judge the prevalence of tuberculosis.

### Mortality rates

In the past, mortality figures were recorded and had value. Even before the tubercle bacillus was isolated in 1882 the reported mortality from tuberculosis in England and Wales was falling by about 1% annually between 1861–65 and 1876–89 [95]. The rate of fall increased in subsequent years in developed countries in the absence of any specific form of intervention. The fall has been attributed to changes in social circumstances, with improvements in nutrition and more particularly alleviation of overcrowding. Mortality from tuberculosis in Scotland and England

and Wales is shown in Fig. 16.4. The continuing decrease in mortality with time is only partly attributable to the introduction of adequate chemotherapy in the early 1950s. Adverse social influences are seen in the documented increases in mortality during the two world wars; favourable social influences, though unquantifiable, have undoubtedly operated since and these, along with improvements in case detection and chemotherapy, have improved the mortality figures.

Deaths still occur from tuberculosis in developed countries [96]. In the USA almost 10% of patients with tuberculosis in 1983 were recorded as dying from the disease [97]; in the UK 15% of white patients with tuberculosis died, although review of death certificates revealed that only half of these patients actually died from, rather than with,

tuberculosis [12,98]. Patients who die in developed countries tend to be older and to have reactivated pulmonary tuberculosis; often there is delay in diagnosis to the extent that it may only be made at autopsy [96–98].

Gryzbowski [99] has outlined his view of the impact of a tuberculosis epidemic on a population (Fig. 16.5). An initial soaring increase in mortality eventually reaches a plateau and subsequently declines without intervention. This may be due to the elimination of susceptible individuals and natural selection. The decline in mortality will continue and can be accelerated by effective chemotherapeutic intervention; ineffective chemotherapy may actually slow the rate of decline by generating a population of infectious individuals who transmit drug-resistant bacilli to the population at large. The possibility that the ineffective application of chemotherapy in the epidemic of HIV-associated tuberculosis in the developing world may exacerbate the tuberculosis problem via this mechanism is one of the reasons why the WHO declared tuberculosis a global emergency in 1993 [100].

The characteristics of an epidemic of tuberculosis at its height are:

- 1 high rates, such as 1% mortality per annum, 1–2% incidence and an annual risk of infection of 15–25%;
- 2 no high-risk groups, although young adults are most often affected;
- 3 most disease is due to recent infection.

This contrasts with countries where tuberculosis is in decline, which are characterized by low rates and high-risk groups such as older men, where disease is due to reactivation rather than recent infection. Alaska is an

**Fig. 16.5** Impact of a tuberculosis epidemic on mortality from tuberculosis in a population. See text for explanation. (From Gryzbowski [99].)

example of a population in which tuberculosis mortality reached a plateau during the period from the 1920s to the 1950s with a death rate of 650 per 100 000, tuberculosis accounting for 35% of all deaths among Eskimos [101,102]. Case finding and treatment have since made a dramatic impact on these figures [103], thus emphasizing what can be achieved if chemotherapy and public health measures are properly utilized.

### Notification rates

If death rates are of little value in assessing the epidemiological behaviour of tuberculosis, then what of notification rates? Notification of tuberculosis has been compulsory in most developed countries for over half a century but is not yet reliably established on a national basis in most developing countries. Notification rates mirror mortality rates, with a decline well established before the introduction of chemotherapy and corresponding increases in rates during the two world wars. Local notification practices vary, making comparison even within, and certainly between, countries difficult. The author's own experience of patients notified as having pulmonary tuberculosis confirms the finding that 50–60% of patients have positive cultures to support the diagnosis [104]. Many have suggestive pulmonary lesions, positive tuberculin tests and an appropriate response to chemotherapy although bacteriologically negative. A few have primary tuberculosis and negative bacteriology and some are notified because they have only a positive tuberculin test and are contacts of an infectious case. The latter should not be included in notification rates. Notification rates are not necessarily the most reliable indicators of the extent of tuberculosis in the community but where practices of notification are consistent they may well be the most easily obtained indices of trends of disease. As the result of an initiative by the International Union Against Tuberculosis and Lung Disease and the WHO, the definitions of cases of tuberculosis to be notified and utilized for the purpose of surveillance have recently been clarified and are given in Table 16.3 [105].

The trends of notification rates with time for Scotland and England and Wales are shown in Fig. 16.6. In both

**Table 16.3** Case definitions for tuberculosis recommended for surveillance purposes. (From Rieder *et al.* [105].)

Definite case: culture-confirmed disease due to <i>Mycobacterium tuberculosis</i> complex
Other than definite cases: must meet both of the following criteria:
Clinical judgement that the patient's clinical and/or radiological signs and/or symptoms are compatible with tuberculosis
Clinical decision to treat with a full course of antituberculosis chemotherapy

**Fig. 16.6** Notification rates for respiratory tuberculosis in Scotland and England and Wales 1913–85.

Region	People infected (millions)	New cases	Deaths
Africa	171	1 400 000	660 000
Americas*	117	560 000	220 000
Eastern Mediterranean	52	594 000	160 000
South-East Asia	426	2 480 000	940 000
Western Pacific†	574	2 560 000	890 000

**Table 16.4** The global toll of tuberculosis, 1989–90. (From Anon. [2].)

countries a downward trend of 8–10% per annum continued from the 1950s until the mid-1980s, when tuberculosis notifications plateaued [106,107]. A similar phenomenon has been observed in other European countries [108] as well as in the USA [109]. The reasons for this reversal of the downward trend in notifications varies for each country: in Holland and Switzerland, for example, immigrants and refugees form a significant proportion of notifications [110]; in the USA, HIV and a decline of tuberculosis control services has been implicated [8]. In Scotland, immigration and HIV are not causes, although more tuberculous disease among the growing numbers of an increasingly elderly older population may be a factor [111]. In England and Wales, the picture is less clear but urban overcrowd-

ing, immigration and deprivation may all be factors [112,113].

The global toll of tuberculosis in terms of new cases (or estimated notifications) and deaths is given in Table 16.4 and the estimated worldwide notification rates are shown in Fig. 16.7. Notification rates of greater than 100 per 100 000 are almost universal in Africa and Asia and are also found in parts of South America. Finally, Fig. 16.8 shows the relationship of notification rates to age and sex for a rural south Indian population and the white and non-white population in the USA [114,115]. Male and female rates are much the same from childhood through young adult life. Thereafter male rates become increasingly greater than female rates. In the USA, non-white

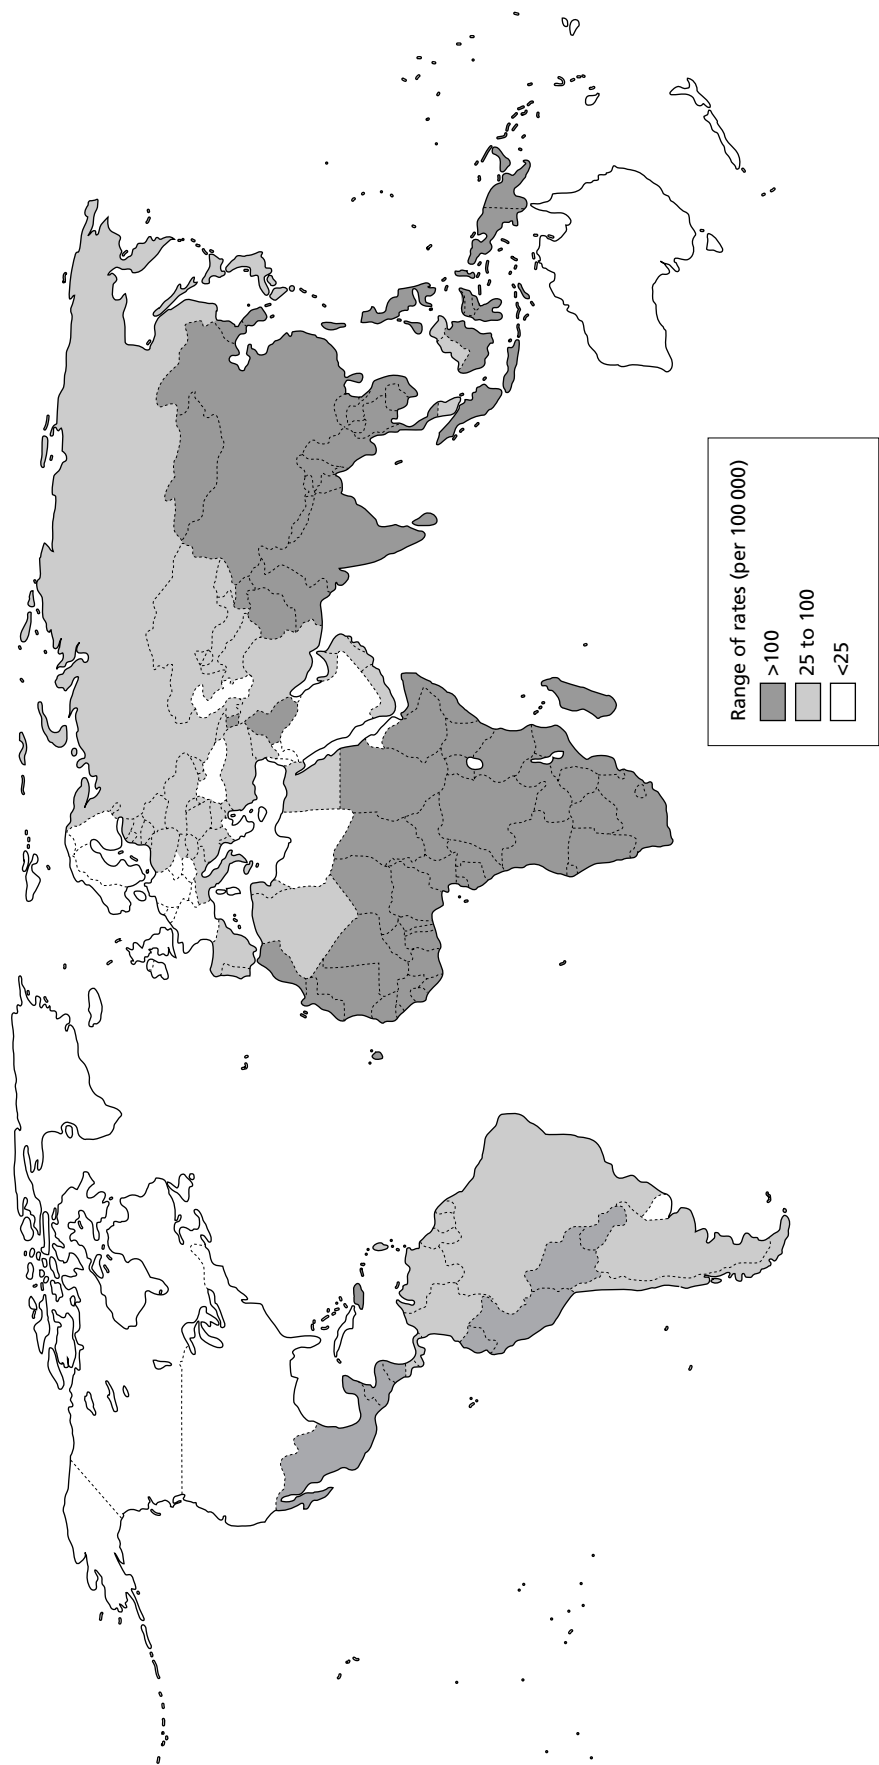

Fig. 16.7 World estimated tuberculosis notification rates 1990. (From WHO.)

rates for both sexes are consistently higher than those for whites.

### Risk of tuberculous infection

The annual tuberculosis infection rate or annual risk of infection is the best single indicator of the status and trend of tuberculosis in both developed and developing countries. It indicates the proportion of the population that will be primarily infected or reinfected in the course of 1 year and is usually expressed as a percentage. The rate is derived from the results of tuberculin testing (see later) [116–118], and to obtain reliable estimates of rates and changes over a particular period several tuberculin

surveys are required at intervals in representative samples of non-BCG-vaccinated subjects of the same age who are tested by the same technique. In countries with high rates of infection, only a small sample of children, say 4000 aged 10 years, would be needed to estimate the rate. Where the prevalence of tuberculous infection is low, a larger sample of older children would be needed.

The risk of tuberculous infection in developed countries is now very low, being less than 0.5% per annum in the majority, 0.1–0.3% in most and less than 0.1% in a few countries [119]. The risk of tuberculosis in these countries continues to decline by about 10% per year, studies from The Netherlands suggesting that the trend in risk has closely followed an exponential decline for the last 25 years [120].

In developing countries much higher rates are found. The annual risks of infection for the richest and the poorest countries are shown in Table 16.5 [2]. In most industrialized countries the annual rate of infection is now below 0.1% and continues to decline by 10% per annum. In sub-Saharan Africa, the annual risk of infection may be as much as 2.5% or more, and in the present context of increasing tuberculosis notifications due to the HIV epidemic is increasing rather than decreasing. The most striking decrease in the risk of tuberculous infection ever recorded is that seen in the native population of Alaska between 1950 and 1970 when the rate fell from 25% to 0.3% [121], a valuable illustration of the impact that efficient antituberculosis measures can have even in high prevalence areas.

**Fig. 16.8** Tuberculosis notification rates by sex and age, south India, 1961–68; and by race, sex and age, USA, 1978. [From National Tuberculosis Institute Bangalore [114] and Centers for Disease Control [115].]

### Trends in the pattern of tuberculous infection

#### Developed countries

Styblo [122] has estimated the number of persons infected annually with tubercle bacilli in the decades from 1910 to 1975 in The Netherlands; this fell from 11 310 per 100 000 in 1910 to 25 per 100 000 in 1975, a decrease of 99.88%. This

Areas	Annual risk of infection		Health resource availability
	Current level (%)	Annual decline trend (%)	
Industrialized	0.01–0.1	>10	Excellent
Middle income in Latin America, West Asia and North Africa	0.5–1.5	5–10	Good
Middle income in East and South-East Asia	1.0–2.5	<5	Good
Sub-Saharan Africa and Indian subcontinent	1.0–2.5	0–3	Poor

**Table 16.5** The epidemiological pattern of tuberculosis: annual risks of tuberculosis infection 1989–90. (From Anon. [2].)

dramatic change in the risk of tuberculous infection in The Netherlands (and by implication in other developed countries) has led to profound changes in the prevalence of infection in the indigenous population. The estimates of prevalence of tuberculous infection in the cohorts born in the year 1910 and succeeding decades for those aged 5, 10, 20, 30, . . . , 80 years are shown in Fig. 16.9. For individual cohorts each curve is similar, in that it rises steeply during childhood, less steeply during adolescence and after about 25 years of age is very nearly flat. The prevalence of tuberculous infection at individual ages has changed substantially during the 50 years. For example, the prevalence of infection at age 20 years was 77% for the cohort of 1910 but had decreased to 3.8% for the cohort of 1950 and would have decreased to about 1% for the cohort of 1960 (in 1980). The prevalence rates have also fallen steeply for 30–40 year olds but in 50-year-olds they remained unchanged at about 85% until the 1960s when they reached their 'turning point', with the present rate now being about 50%. For 70 year olds it is possible to calculate from the figure that it will take about 30 years before an infection rate of only 20% will be achieved. These estimates are clearly useful in illustrating how the pattern of infection changes with time by age cohorts in a developed country and allow one to forecast the extent of tuberculous infection in the future, assuming that the present pattern of declining risk continues. At present, in most developed

**Fig. 16.9** Estimated prevalence (%) of tuberculosis infection in cohorts born 1910–60 in 1945, 1975 and 2005, The Netherlands. See text for explanation. (From Styblo [122].)

countries, any rise in tuberculosis notifications secondary to HIV infection has not influenced trends in annual risk of tuberculous infection.

### Developing countries

With certain assumptions, estimates of prevalence with a similar pattern can be derived for the developing countries. Assuming an average annual infection rate of 3% and a 5% annual decrease in risk from 1981 to 2010 (an optimistic assumption in the light of the impact of the HIV epidemic), it is possible to illustrate how tuberculous infection might behave in the future in a developing country (Fig. 16.10). Up to 1980 the prevalence of infection remains constant for all age groups; however, with the assumption of a 5% decrease in the annual risk of infection, decreases in prevalence are seen so that, for example, only 14% of 10-year-old children born in 1990 will be infected in 2000 compared with 26% of the cohort born in 1970. It can be calculated that a 5% annual decrease in the risk of tuberculous infection would reduce the overall risk of infection from 3% in 1980 to about 0.7% in 2010, thus beginning to approach the situation currently found in developing countries. The value of estimating not only the

**Fig. 16.10** Calculated prevalence (%) of tuberculous infection in a developing country for cohorts born in 1910, 1930, 1950, 1970, 1980, 1990 and 2000 at ages 5, 10, . . . , 60 years assuming a constant decrease in risk between 1981 and 2010. See text for explanation. (From Styblo [122].)

risk of tuberculosis in developing countries but also its trend, both as a measure of the impact of antituberculosis programmes and as a predictor of the future extent of tuberculous infection in the community, is thus seen.

### Risk of disease after infection

Time trends in the risk of developing tuberculosis after infection are difficult to ascertain because of differences in tuberculin testing methods, criteria for a positive reaction and the age structure of the populations. However, among untreated tuberculin-positive household contacts of active cases the annual new case rate was 1220 per 100 000 in the first year, falling to 310 per 100 000 for the next 2 years and finally to 160 per 100 000 in the sixth and seventh years [123]. This finding confirms the observation in the British Medical Research Council study that the majority of cases occur in the first year after infection [93,94].

Geographic variation in the extent of disease after infection is well recognized and largely unexplained. In untreated tuberculin-positive Eskimo reactors, attack rates of over 1500 per 100 000 were recorded in the first year of observation [123]. This compares with attack rates of 101 per 100 000 in south India [114], 61 per 100 000 in Georgia and Alabama [124] and only 29 per 100 000 in Denmark [125].

Case rates among tuberculin reactors vary markedly with age [123,126,127], being high in the early years of life, troughing at 10–12 years of age and peaking again in late adolescence and early adult life. Thereafter case rates decrease to a relatively low level that persists into old age.

### Impact of HIV infection on the epidemiology of tuberculosis in developing countries

HIV infection is remarkably common in the developing world [6]; surveys of apparently healthy blood donors and other subjects have shown prevalences of HIV positivity as high as the 23.5% of women in the Rakai district of Uganda [128]. In the developing world the principal mode of transmission of HIV infection is heterosexual [128] so that the young and sexually active are infected; the WHO has calculated that over 9 million adults were infected with HIV in Africa by December 1993, 2.5 million in Central and South America and 2 million in South-East Asia and the Western Pacific [6]. Since most (82%) of the 1700 million infected worldwide with tuberculosis are found in the developing world, a substantial minority, if not a majority, of those acquiring HIV infection will already have been infected with tuberculosis [3]. The relative risk of developing active tuberculosis in those dually infected lies between 6 and 100 [129] and is over 20 in two studies of Zairean and Rwandan women [130,131]; in Haiti the risk ratio was 16 [132].

Most disease occurring in the dually infected is believed to be due to reactivation of pre-existing tuberculosis infection, although evidence is mounting that, especially in high-prevalence areas, disease due to new or reinfection with tuberculosis may occur in those infected with HIV [133–135]. On the basis of available information it is possible to calculate on a conservative basis that tuberculosis cases will increase by 50–60% in sub-Saharan Africa by the year 2000 [136]; this is borne out by reports of annual notifications from several of these countries (Fig. 16.11) and is being monitored by measuring the annual risk of infection in Tanzania [137]. Surveys of HIV infection in tuberculosis patients in Zambia [138], Kenya [139] and Uganda [140] have shown HIV seropositivity in 27–50% of patients. HIV-associated tuberculosis is no more infectious than non-HIV-associated tuberculosis [141].

The clinical features of HIV-associated tuberculosis are given in Chapter 17 and the treatment of HIV-associated tuberculosis is discussed in Chapter 19. Preventive therapy for HIV-positive patients is discussed later in this chapter under chemoprophylaxis.

### Measurement of infection: tuberculin skin testing

Tuberculin, a broth culture filtrate of tubercle bacilli, was first prepared by Robert Koch in 1880 and wrongly promoted as a cure for tuberculosis [142]. Subcutaneous injection of tuberculin into patients with tuberculosis resulted in severe systemic upset whereas non-tuberculous individuals showed few or no symptoms. The original preparation of old tuberculin was used until the 1930s when Seibert prepared a purified protein derivative (PPD). This

Fig. 16.11 Rise in annual notifications of all forms of tuberculosis in four African countries 1985–91 (WHO, unpublished data).

proved to be a potent, stable tuberculin without sensitizing properties and in 1941 a single large lot of PPD from a single strain of the human tubercle bacillus was made [143] and deposited as the International Standard for Purified Protein Derivative of Mammalian Tuberculin to be known as PPD-S. Other standard PPDs include PPD-RT23 prepared in Denmark for international use and the British Standard preparation known as PPD-Weybridge. Problems with the adsorption of tuberculin to glass and plastic surfaces that resulted in false-negative reactions have been resolved by the addition of small quantities of the detergent Tween 80 to the solution. The use of the tuberculin test has been reviewed extensively [144–47].

### Specific and non-specific tuberculin skin reactions

The early days of tuberculin skin testing were plagued by the problem of false-positive skin reactions [144]. In 1941, a study of quantitative tuberculin skin sensitivity in various Ohio and Minnesota populations was published [148]. This study found that almost everyone would react to tuberculin if sufficiently high doses were used for testing. However, patients with tuberculosis and many of their contacts reacted to a relatively low dose of PPD, whereas those without tuberculosis or lacking contact reacted only to higher doses. It was concluded that high-dose reactions were probably 'not due to infection with the tubercle bacillus'. As a result of this and other corroborating studies the dose of 0.1 µg of PPD or 5TU became accepted in North America as the dose most likely to distinguish true from false positives. Application of the 5-TU skin test and a 250-TU skin test to student nurses throughout the USA confirmed the value of the test [149]. The nurses were divided into three groups on the basis of their tuberculosis contact status: no contact, intermediate contact and close contact. Positive reactions to 5TU increased from 10% in those with no contact to 41% in those with close contact, whereas similar numbers in all three groups had positive reactions to 250 TU. The positive findings with 5TU were similar in both northern and western states and in south-eastern states. However, positive reactions to 250 TU were 29% in northern and western states but 67% in south-eastern states, leading to the con-

clusion that the sensitivity elicited by high doses of PPD-S represented infection by a different but antigenically related organism that was highly prevalent in some geographical areas (south-eastern USA) and apparently was not pathogenic for humans.

Using the Mantoux technique with 5TU of PPD-S or its equivalent, surveys of tuberculosis patients throughout the world have shown a remarkable degree of concordance in the size of skin reactions [150]. There is a normal distribution of reactions, with a mean ranging from 12.8 mm in south India to 18.8 mm in the Sudan (Fig. 16.12). In the general population the problem of how to interpret the size of the skin reaction to 5TU remains and is well illustrated by reference to studies in tuberculous patients and US Navy recruits [151–153]. In the patients with tuberculosis, with the exception of a few who failed to react, the distribution of reactions to 5TU is essentially normal with a single mode at induration sites of 16–17 mm in diameter (Fig. 16.13a). In US Navy recruits with household exposure to tuberculosis the distribution of reaction sizes is bimodal (Fig. 16.13b), with the right-hand portion similar to reaction sizes of tuberculosis patients but at a much lower level. In Navy recruits who deny household exposure to tuberculosis there is no evidence of bimodality of reaction sizes, with a majority of low reaction sizes (Fig. 16.13c). However, it is possible to sketch in the hidden right-hand portion of the distribution caused by tubercu-

Fig. 16.12 Frequency curves of sizes of reactions to 5 TU of PPD for patients in tuberculosis hospitals in Sudan (—•—), south India (---) and averaged for all countries (—). (From WHO Tuberculosis Research Office [150].)

Fig. 16.13 Percentage distribution of diameters of induration to 5 TU of PPD-S: (a) tuberculous patients with positive sputum cultures; (b) white male US Navy recruits, 17–21 years of age, with a history of contact with tuberculosis; (c) white male US Navy recruits, 17–21 years of age, with no history of contact with tuberculosis (note different scales on y axes). (From Comstock *et al.* [152], Rust & Thomas [153] and American Thoracic Society [154].)

lous infections. From these studies it is clear that if the level of positivity for the 5TU test is set at 10mm, most cases of tuberculous infection or specific skin test reactions will be included. However, there is an overlap at 5–10mm of induration of non-specific and specific tuberculin reactions. This has led to the recommendation that where the index of suspicion for tuberculous infection is high, as in close contacts of tuberculosis or in those with chest X-ray changes consistent with tuberculosis, then a reaction size of 5mm should be used to separate non-significant from significant tuberculin skin test reactions. If this is done, few persons infected with tuberculosis are classified as having insignificant reactions and few persons not infected with tuberculosis are classified as having significant reactions [145,154,155].

The cause of the non-specific or weak tuberculin reactivity clustered in the south-eastern USA is now thought to be infection with environmental atypical mycobacteria such as the *M. avium-intracellulare/scrofulaceum* complex organisms [156,157]. Skin testing of Navy recruits with PPD-S, PPD-B (an antigen prepared from the Battey bacillus, *M. intracellulare*) and PPD-G (an antigen prepared from the 'Gause' strain of *M. scrofulaceum*) showed that the geographical distribution of reactors to PPD-S was quite different to that of reactors to the atypical antigens [158]. PPD-S reactors were concentrated in large metropolitan areas, in Appalachia, along the Mexican border and in a few other isolated areas. In contrast, reactors to the atypical antigens were concentrated in the south-eastern USA.

Bimodal distributions of tuberculin reactions have now been reported from many countries [150,159,160], with considerable geographical variation. Non-specific sensitivity ranged from less than 10% in Denmark and northern USA to over 90% in the Philippines, the Sudan and Vietnam. It was relatively high (70–80%) in some parts of India and relatively low (20–30%) in England and Mexico.

### Techniques and interpretation of tuberculin tests

Tuberculin skin testing may be performed by the intradermal injection of PPD (Mantoux test) or with multiple puncture devices utilizing Old Tuberculin (Heaf and Tine tests).

#### Mantoux test

The Mantoux test is performed by intradermal injection of 0.1 mL of PPD containing 5 TU into the volar surface of the forearm using a 27-gauge needle with a plastic or glass syringe. The injection should be made just beneath the surface of the skin and produce a wheal of 6–10mm in diameter. The test is read at 48–72 h. The reaction consists of erythema and induration. The erythema should be dis-

regarded and the diameter of the induration measured in millimetres. Induration of greater than 10mm is virtually diagnostic of past or present tuberculous infection. Lesser degrees of induration may be due to non-specific sensitivity, but where the index of suspicion for tuberculosis is high (as discussed above) reactions above 5mm should be considered positive.

Where skin tests are performed in contacts of infectious cases of tuberculosis, subjects with initial skin test reactions of less than 10mm should be retested at 6 weeks, when an increase in reaction size to greater than 10mm and by an increase of at least 6mm is taken to indicate skin test conversion due to recent infection [161]. The classification and interpretation of skin reactions to 5 TU of tuberculin is shown in Table 16.6 [145].

In the UK, the Mantoux test has traditionally been performed with 10 TU of PPD. Induration of greater than 5 mm is considered to be significant and more than 15 mm to represent definite tuberculous infection (cf. Table 16.6). BCG vaccination is still universally employed in the UK and vaccinated individuals usually have positive Mantoux tests, with induration ranging from 5 to 14 mm. Induration greater than 15 mm in response to a Mantoux 10-TU test in a previously BCG-vaccinated individual should be considered to represent tuberculous infection (usually presumed subsequent to the BCG vaccination) [162].

**Table 16.6** Interpretation of skin-test reactions to the 5-TU Mantoux test. Reactions in the following categories of patients should be considered significant and indicative of tuberculosis infection.

---

#### *Induration >5 mm*

HIV-infected persons or persons with risk factors for HIV and unknown HIV status  
Persons who have had close recent contact with an infectious case of tuberculosis  
Persons who have chest radiographs consistent with old healed tuberculosis

#### *Induration >10 mm*

Persons with risk factors for tuberculosis other than the above, including the following:  
Foreign-born persons from high-prevalence countries  
Intravenous drug users  
Socially deprived or ethnic minority groups  
Residents of long-term care facilities  
Persons with medical conditions predisposing to tuberculosis, e.g. silicosis, gastric surgery, chronic renal failure, diabetes mellitus and immunosuppressive therapy  
Other high-risk populations

#### *Induration >15 mm*

Considered positive in all persons (including those who have had previous BCG vaccination)

---

### Heaf test

The multipuncture test of Heaf is carried out with an instrument (gun) that carries a small plate to which are fixed six short steel needles. A disposable head is available that performs favourably in comparison with the original fixed-head Heaf gun and its use avoids the need for sterilization [163]. On release of a spring the needles puncture the skin to a depth of 2 mm or, by adjustment, to a depth of 1 mm in children. Penetration of the tensed skin takes place through a thin film of applied solution, either PPD in a strength of 2 mg/mL or pure Old Tuberculin to each 1 mL of which one drop of 1:1000 epinephrine (adrenaline) has been added. The test is best read between 3 and 7 days, can be read and self-reported by the patient [164], and is graded as follows (Fig. 16.14).

Grade I: at least four separated papules.

Grade II: the papules are confluent to form a ring.

Grade III: the ring is filled in at the centre with induration that may spread outwards from the ring.

Fig. 16.14 Typical Heaf test reactions, grades I-IV.

grade IV: as for grade III with vesiculation or ulceration of the skin and extended induration.

Grade III and IV Heaf reactions are usually indicative of past or present tuberculous infection. Grade I and II reactions are not usually associated with infection by human tubercle bacilli and may be due to other mycobacteria [165]. In populations vaccinated with BCG most individuals develop Heaf grade I or II rather than grade III or IV reactions [166] (Fig. 16.15).

### Booster effect or phenomenon

Repeated tuberculin testing of non-sensitized individuals does not sensitize them to tuberculin [167]. Delayed hypersensitivity to tuberculin, once established by mycobacterial infection, may gradually wane over the years. A recent study in Edinburgh showed 55% Heaf grade III or IV reactors in the age group 45-65 years but only 37% positive at the same level in those aged over 65 [168], reflecting the gradual waning of skin-test reactivity with passing years [169]. Reaction to a tuberculin skin test many years after original infection may not be significant, although a subsequent test may prove to be positive, the lymphocytes having been 'switched on' by the initial test, giving an apparent 'conversion' or development of tuberculin hypersensitivity. This may be wrongly interpreted as a 'skin-test conversion' and hence primary tuberculous infection. As implied by the Edinburgh observations [168], the booster phenomenon is most likely to occur in middle or advanced age [169]. It can be seen as soon as 1 week after the initial stimulating test and can persist for 1 year

Fig. 16.15 Histogram showing percentage of reactions by Heaf grade in groups of children before and after receiving BCG vaccination. (From Davies & Leitch [147].)

or more [170]. Where repeat tuberculin tests are used in surveys (most commonly with hospital employees in the USA), it is important to eliminate this effect. Where employees are young (mean age 26) Valenti *et al.* [171] have shown that boosting (i.e. conversion of skin test at 1 week) does not occur. Where there is a wide range of ages in employees, apparent skin-test conversion is age related [172], reflecting the booster phenomenon; if boosters are eliminated, converter rates fall from 9% to 3% [173]. These conversion rates are still too high but err on the side of safety. A further study found a 5-year conversion rate of 7.1%. However, conversion was commoner in non-white 46–64 year olds of low social class and was considered to represent largely a contribution from boosting and, possibly, an indeterminate contribution from exposure in the community at large [174].

The booster phenomenon presents a real problem of interpretation in contacts. Should an elderly person in contact with a smear-positive case with an initially negative reaction to 5TU or to the Heaf test be considered to have converted (and therefore developed primary infection) if they are subsequently positive? The author's own policy is simply to observe for 1 year with chest films if the second tuberculin test is positive (they have probably boosted) and to treat for tuberculosis if the chest film is positive. If all tuberculin-positive contacts in Edinburgh were given chemoprophylaxis, a substantial minority of the contact population would be exposed to drug therapy [168].

Causes of false-negative tuberculin tests

As already discussed, patients with active tuberculosis do not invariably have positive tuberculin skin tests. False negatives are most commonly seen in those with overwhelming disease, miliary or cryptic miliary disease and tuberculous meningitis. Many other factors relating to the patient and also to the performance of the test may be implicated and these are listed in Table 16.7. The subject has recently been reviewed [67].

Control and prevention

The most powerful weapons for controlling and preventing tuberculosis are case finding and treatment with a view to preventing the spread of *M. tuberculosis* from smear-positive cases. Prevention of infection by *M. bovis* can be achieved by the establishment of tuberculosis-free herds and the pasteurization of milk [175]. Rarely, measures may have to be taken against other animals, as in the south-west of England where wild badgers became heavily infected with *M. bovis* and were believed to be responsible for reinfecting cattle [176]. Transmission of disease due to *M. bovis* has also been recorded from farmed elk in Canada [177–179] and in marine park seals

Table 16.7 Potential causes of false-negative tuberculin reactions.

<i>Patient-related factors</i>	
Infections	
Viral, e.g.	mumps, measles, chickenpox, influenza, HIV
Bacterial, e.g.	typhoid, brucellosis, typhus, leprosy, pertussis, overwhelming miliary or cryptic miliary tuberculosis, tuberculous meningitis
Fungal, e.g.	South American blastomycosis
Live virus vaccinations, e.g.	
measles, mumps, polio	
Metabolic disease, e.g.	
chronic renal failure	
Nutritional defect, e.g.	
protein malnutrition	
Lymphoid disease, e.g.	
Hodgkin's disease, lymphoma, lymphocytic leukaemia, sarcoidosis	
Drugs, e.g.	
corticosteroids and immunosuppressive agents	
Age, e.g.	
newborns and elderly	
Miscellaneous, e.g.	
stress, surgery, burns, graft-versus-host reaction	
<i>Tuberculin-related factors</i>	
Improper storage (exposure to light and heat)	
Improper dilution	
Chemical desaturation	
Contamination	
Adsorption (add Tween 80)	
<i>Method of administration factors</i>	
Injection of too little antigen	
Injection too deep	
<i>Reading and recording factors</i>	
Inexperience in reading	
Bias in reading	
Error in recording	

in Australia [180]. BCG vaccination and chemoprophylaxis also make important contributions to the control of tuberculosis.

Case finding

Developed countries

It is now recognized that mass screening of the general population by X-ray examination, although identifying cases of tuberculosis, makes no substantial impact on the number of new cases arising in that population [181]. The evidence for this observation is derived principally from studies in Kolin in the former Czechoslovakia [36,182], where 95% of the population over 14 years old had chest radiography at 3-year intervals between 1961 and 1972. All identified cases were treated. The number of infectious (smear-positive) cases did not differ significantly from year to year between 1960 and 1972, i.e. despite repeated 'cleaning-up' of the population by radiographic detection of disease and treatment, new cases of smear-positive disease developed in the years between the screenings. The methods of discovery of smear-positive cases in Kolin

**Table 16.8** Mode of detection of smear-positive tuberculosis cases in Kolin, Czechoslovakia, 1961–69 and The Netherlands, 1951–67. (From Meijer *et al.* [183].)

Country or area	Period of observation	Number of smear-positive cases	Percentage of smear-positive cases discovered by			
			Symptom cases	Chest clinic check-ups	Mass radiography	Other
Kolin study	1961–69	193	45	21	25	9
Netherlands	1951–55	6027	58	12	14	15
	1956–61	3823	57	15	13	14
	1962–67	2460	54	17	15	13

and also in The Netherlands, where screening by mass miniature radiography was also carried out, are shown in Table 16.8 [183]. In both studies the commonest method of discovery was presentation with symptoms. Smaller numbers were detected by chest clinic check-ups (e.g. contacts, recent converters and those with ‘fibrotic’ lesions) and by mass radiography. Therefore case finding in the general population most frequently results from X-ray and sputum examination of patients presenting with symptoms. Although mass radiography is not indicated as a case-finding method in the population at large, there are clear indications for the screening of selected populations. Such selected populations may be divided into high-yield and danger groups.

### High-yield groups

#### *Symptom group*

This consists of patients who have symptoms suggestive of tuberculosis, for example patients presenting with a cough that fails to respond to conventional treatment; such patients should be referred for a chest radiograph. In Edinburgh it has proved extremely valuable to have a facility to which general practitioners can easily refer patients for X-ray examination. Delays in referral for investigation, though common, are infrequently reported [184,185].

#### *Contacts*

It is most important following notification of a case of tuberculosis that appropriate contact procedures be initiated with a view to identifying other associated cases of tuberculosis. If the first notified or index case is one of primary tuberculosis, then a source case is sought; if the index case has postprimary tuberculosis then, although a source may still be searched for, the concern is that other contacts may have been infected by the index case. Studies in the UK [186–193] have shown that up to 10% of all new cases of tuberculosis are diagnosed by contact-tracing procedures, although these may be less rewarding in areas where the incidence of tuberculosis is low [194,195].

Contacts should be screened by tuberculin testing and chest film. Negative skin reactors should be retested at 6 weeks to exclude the possibility of recent primary infection. Skin-test conversion merits chemoprophylaxis. Priority should be given to household and close family contacts of smear-positive cases of pulmonary tuberculosis [196,197] where 5–14% of contacts have been found to have disease [186,193,198–201]. The extent of screening may be determined by the infectivity of the index case; if evidence of infection is found in close contacts the search should be extended, the ‘stone in the pond’ principle [202]. Screening of close contacts of all other cases of tuberculosis with a single chest radiograph, though less productive, is nevertheless recommended [32,33]. Screening should be extended to casual contacts of smear-positive cases but is not necessary for casual contacts of smear-negative or non-respiratory tuberculosis. Tuberculin-positive contacts with normal chest films should have further films taken at intervals for 1 year, a practice that detects further cases in the UK [33]. In the UK, it is usual to offer BCG vaccination to tuberculin-negative contacts [33]. In the USA, it is usual to offer chemoprophylaxis to tuberculin-positive disease-free contacts [32]; in the UK, this is recommended for those aged under 16 years [33].

Recent developments in DNA fingerprinting of *M. tuberculosis* [203] have allowed more detailed examination of patterns of tuberculosis transmission in communities in North America [204,205] and Switzerland [206]. Such studies have revealed the limitations of conventional contact tracing procedures and will undoubtedly continue to yield valuable epidemiological information [207].

#### *Inhabitants of lodging houses, prisons and mental institutions and the homeless*

Tuberculosis is more common in the population variously referred to as the homeless or ‘down and outs’ and in lodging-house or hostel dwellers, among whom alcohol and drug abuse are often commonplace [208–214]. Incidence rates of active tuberculosis may be as high as 2000 per 100 000 [215]. The advent of HIV infection among intravenous drug abusers in this population has led to a further increase in tuberculous disease [216] and has

focused attention on the marked deficiencies in the public health services offered them [217,218]. These individuals are notoriously unreliable, frequently moving address and usually hostile to, and suspicious of, the attentions of the health services. In the USA, skin-testing programmes with chemoprophylaxis for skin test-positive individuals have been suggested [219] and successfully implemented [220]. The threshold of suspicion for tuberculosis in this population should be set low, with early bacteriological and radiological investigation followed by supervised or directly observed treatment of disease [221]. The use of BCG vaccine has been suggested [222]. Staff working with this population should be protected by BCG vaccination or annual tuberculin testing, with chemoprophylaxis for converters. In either case they should be educated to present early for radiographic examination if they develop symptoms.

Homelessness apart, it is increasingly obvious that social deprivation in the so-called developed world continues to be a major contributor to the burden of tuberculosis cases [223] as exemplified by recent reports from Leeds [224,225] and London [226], as well as from England and Wales as a whole [113].

The increasing prevalence of HIV infection has focused attention on the possible consequences to the prison service of incarcerating individuals with dual tuberculous and HIV infection who are predisposed to the risk of developing active tuberculosis, with all the attendant risks of transmission of tuberculosis to other inmates and staff [227]. Clear guidelines have been issued in both the UK [33] and the USA [228] to address this situation. A report from Spain, where prisoners had a high prevalence of HIV infection (30%), found that 2.7% of prisoners had active tuberculosis on admission to prison [229].

Residential facilities, such as homes for the mentally ill or the handicapped, are also potential sites for the spread of tuberculous infection and disease. Radiological screening of such patients in the UK ceased many years ago as it proved unproductive, almost certainly reflecting the overall decrease in tuberculous infection. The occasional identified case leads to prompt and usually unproductive contact screening, which is nevertheless reassuring to all concerned. Chemoprophylaxis of the resident population has been successfully employed in the past [230].

#### *Immigrants and refugees*

In 1993 tuberculosis notifications rates in England and Wales were 4.3 per 100 000 for whites, 115 per 100 000 for the Indian ethnic group and 135 per 100 000 for the Black African group [231]. Similarly in the USA, in comparison with whites tuberculosis was four times more common in Hispanics, five times more common in Amerindians, six times more common in Blacks and 11 times more common

in Asians and Pacific Islanders [232–237]. Recent immigrants from high-prevalence areas should therefore be screened by chest radiography and/or tuberculin testing in order to detect cases of active tuberculosis and permit the prescription of chemoprophylaxis where it is deemed appropriate [110]. Tuberculosis rates so determined have been found to be high in, for example, recent Asian immigrants [238] and South-East Asian refugees [239]. The effects of war are well known [240].

Ideally, screening should be undertaken at the port of entry where this is possible, as in Switzerland [241]; in many countries, including the UK [242], such screening is incomplete and it is essential that the port authorities pass information on all new immigrants to the relevant authorities in the district of intended residence. Such official information on new immigrants can be supplemented by local intelligence [33] and allow the prompt implementation of screening and prevention interventions [243]. The ethical considerations of relevance to managing tuberculosis in immigrant and refugee groups have recently been discussed in detail [244].

#### *Elderly in nursing homes*

It has been suggested that the elderly are not only at risk from endogenous reactivation of tuberculosis but also of exogenous reinfection, particularly in nursing homes [245]. Outbreaks of tuberculosis among the elderly in nursing homes have been reported [246] and subsequent studies of such chronic care populations have shown as much as a 5% annual rate of tuberculin skin-test conversion in elderly residents [247,248], with the development of significant disease in those not given isoniazid [248]. The skin-test conversion rate was twice as high in Blacks as whites [249]. Hopewell [250,251] has suggested, on the basis of his own studies of nursing home residents, that these skin-test conversions are apparent rather than real, simply representing an extension of the booster phenomenon. This would be in keeping with reports from Canada [252] and the UK [253] that do not indicate an increased risk of tuberculosis among the institutionalized elderly. Common sense dictates that an awareness of chest radiological status, and the need for bacteriological investigation for tuberculosis where indicated, be promoted in residential institutions for the elderly.

#### *Medical laboratory workers*

The incidence of tuberculosis is five times higher in medical laboratory workers than in the general population and particularly high in those working in pathology departments [254,255]. Such workers may be offered annual screening chest films or, in countries where BCG is not routinely employed, annual tuberculin testing.

### *Danger groups*

Among those whose work is liable to predispose them to tuberculosis and/or bring them into contact with susceptible individuals are the following.

#### *Schoolteachers and those working with children.*

The important consideration in this group is the detection of active pulmonary tuberculosis by medical examination and appropriate investigation of those about whom there is any suspicion at the pre-employment assessment or at any time thereafter [33].

#### *Hospital employees, including doctors, dentists, nurses and other healthcare workers working with patients*

All healthcare staff in regular contact with patients and laboratory workers handling specimens are potentially at risk of contracting tuberculosis, especially those who work with tuberculosis patients or specimens. Pre-employment screening should exclude symptoms of tuberculosis, determine details of BCG immunization and scar status, and include skin testing for those who have not had BCG. Unvaccinated tuberculin-negative workers should receive BCG [33]. Unvaccinated tuberculin-positive workers should only have radiography if they are symptomatic [254]. It is uncommon in the UK for hospital staff to acquire infection from patients [255] and routine periodic chest radiography is not required, except possibly for some categories of pathology and bacteriology laboratory staff. More realistically, such staff, as well as others concerned about contact with an infectious case, should be educated and advised to report early if suggestive symptoms develop. In the UK, guidelines for the occupational health services within the National Health Service have been published [33] and are necessary [256] since cases of tuberculosis still occur in hospital doctors [257–259], some of whom have evaded screening. Such individuals may transmit infection to patients [260]. In the USA, the practice of annual tuberculin testing of hospital employees, with chemoprophylaxis for skin-test converters, is likely to continue [261].

Reports from the USA have indicated a risk to staff of contracting tuberculosis, including multidrug-resistant strains, from patients with HIV infection. In the UK, all such exposed staff must be protected by BCG vaccination or must be known to be tuberculin positive before working with HIV-infected tuberculosis patients [33]. The author, faced with the prospect of contact with multidrug-resistant tuberculosis, would prefer to have had BCG vaccination even though protection is not complete (see below); such a policy has yet to be adopted in the USA.

### **Developing countries**

In the developing countries, where expense precludes the universal availability of chest X-ray facilities, the most rewarding method of case finding is by direct smear examination of sputum from symptomatic cases. This can be done in rural as well as urban areas by suitably trained personnel [262] and has the advantage of identifying the most infectious cases of tuberculosis.

### **BCG vaccination**

BCG was originally a bovine strain of tuberculosis that was attenuated by 230 passages through media containing glycerine and ox bile and was first used in France in the 1920s as an oral vaccine and subsequently as an intradermal injection. It does not prevent infection with tuberculosis but limits multiplication and dissemination of mycobacteria following infection [263].

### **Types of vaccine**

Numerous strains of vaccine are currently available [264,265] and they must be carefully standardized. If the vaccine is too 'virulent', there is a higher incidence of complications; if it is too weak, the tuberculin test conversion rate may be decreased and efficacy impaired. The vaccine must also be given under carefully controlled conditions as the organisms are very susceptible to daylight or sunlight. For many years the standard vaccine was a liquid that was freshly prepared and had to be given within 14 days or less of preparation. Freeze-dried vaccine has now been developed, with the great advantage that it can be kept for longer periods provided it is stored at a temperature of less than 6°C. Deterioration may occur within a day or two at temperatures of 37°C and above, as in very hot climates [266–268].

### **Evidence for efficacy**

The first trial to demonstrate the efficacy of BCG was carried out by Aronson *et al.* [269] on North American Indians in 1936–38 and showed a protective efficacy against death from tuberculosis of 82% for 18–20 years. The second trial by Rosenthal *et al.* [270] in Chicago infants in 1937–48 gave 74% protection over 12–23 years. The British Medical Research Council [93,271,272] controlled trial in urban school leavers showed a 79% reduction in tuberculosis in the vaccinated group over 20 years. Protection was not related to the degree of tuberculin sensitivity induced [273]. In south India, Frimodt-Moller *et al.* [274] obtained a 62% reduction in attack rate.

Less satisfactory results were reported by the United States Public Health Service from controlled trials carried

out in Puerto Rico and the southern USA [275,276]. More recently an extensive trial in south India has demonstrated no protective effect of BCG [277,278]. Whether the failures of these trials are due to differences in vaccine, the high prevalence of possibly protective atypical mycobacterial sensitization in these areas or to study design has not yet been resolved [265,279]. However, numerous additional studies do provide support for a substantial beneficial influence of BCG vaccination [280–284], including a recent meta-analysis [285] that suggested a 50% protective effect.

### Indications for vaccine

In the UK, BCG is still given to schoolchildren aged 13–14 who are Heaf grades 0 or 1 or who show less than 5-mm induration to 10 TU on Mantoux testing [162,284]. In 1989 it was estimated that 4000 vaccinations are given to prevent one case of tuberculosis. The need for universal BCG vaccination of schoolchildren is likely to be reviewed in the near future as the risk of infection and hence the number of cases prevented by BCG diminishes [286].

Other categories of individuals currently offered tuberculin testing, and BCG vaccination if negative, include health service workers, contacts of cases of tuberculosis and those planning to reside in high-prevalence countries. Children and newborns of Asian families in the UK who have an increased risk of exposure to tuberculosis should also be vaccinated.

In developing countries with a high incidence of tuberculosis, the WHO has recommended administration of BCG to neonates or as early as possible to children [287]. The main reason for this recommendation is that BCG has always shown a protective effect in studies in young children [288] and the south India study did not produce any contradictory evidence.

### Techniques of administration

The vaccine is best given by intradermal injection of 0.1 mL (0.05 mL for those <3 months old) in the lower deltoid area. A papule appears in 3–4 weeks that usually remains for a number of weeks and may ulcerate slightly and discharge. There is sometimes slight enlargement of the draining lymph nodes. The tuberculin test should become positive within 3 months. It has been shown that no untoward reaction occurs if tuberculin-positive individuals are vaccinated [289]. This enables mass vaccination to be carried out in a developing country without the necessity for a return visit to have a tuberculin test read.

### Complications

Complications of BCG are very few [290]. Local secondary infection is the commonest and this occasionally gives rise to an abscess or swollen tender draining lymph nodes.

Cold abscess of the draining glands may occur [291]. Short courses of erythromycin or isoniazid are equally effective in the treatment of these local complications [292–294]. Local lupoid reactions may occur, most often under an occlusive dressing. Ultraviolet light is sometimes effective in hastening healing of local lesions. Erythema nodosum and urticaria have occasionally been recorded. Disseminated BCG, which may be fatal, is exceedingly rare and most usually seen in those with disturbances of immunity. BCG should not be given to such individuals or to patients with extensive dermatosis [291,295].

### Chemoprophylaxis

Chemoprophylaxis is the administration of chemotherapy to prevent the development of tuberculous disease [123,296,297]. Primary chemoprophylaxis involves giving chemotherapy to individuals who have not so far been infected. Secondary (or disease) chemoprophylaxis is chemotherapy for individuals with a positive tuberculin test who have been infected in an endeavour to prevent development of disease. These individuals may have a normal chest film or it may show evidence of previous tuberculous infection.

### Mass chemoprophylaxis

Combinations of both primary and secondary chemoprophylaxis or mass chemoprophylaxis have been used in communities with a high prevalence of tuberculosis, with isoniazid treatment applied to the whole population [127,298,299]. Such mass prophylaxis resulted in diminution of the amount of tuberculosis in the treated group when special care was taken to ensure that a high proportion of the population took their medication. In the Greenland trial [298], prophylaxis with isoniazid for 1 year resulted in a 60% disease reduction that persisted for at least 5 years. Isoniazid-resistant strains were not a feature in those subsequently developing disease. In a smaller-scale Canadian controlled trial in Eskimos who are particularly susceptible to the disease, where isoniazid and ethambutol were used three times a week under supervision for 18 months, there were no cases in the treated group over 3 years compared with an annual attack rate of 1.8 per 1000 in the controls [300]. The same regimen of ethambutol and isoniazid thrice weekly for 18 months applied to those with previous tuberculosis or a strongly positive tuberculin test with or without previous BCG resulted in an incidence of tuberculosis of 0.1% per annum in the treated group compared with 1% per annum in the untreated group over a period of 10 years [301]. Though effective in populations with a high prevalence of tuberculosis, such interventions are enormously expensive and therefore inappropriate for developing countries.

### Primary chemoprophylaxis

The use of isoniazid to prevent disease in individuals who have not previously been infected is based on the value of the drug in preventing disease in experimental animals [302–306]. It is infrequently employed, since individuals at risk of infection following exposure to tuberculosis are usually simply tuberculin tested and if negative retested at 6 weeks, when converters are treated and non-converters offered BCG (see p. 495). It is not known whether starting chemotherapy with isoniazid at the time of the first negative tuberculin test is of greater benefit than starting therapy should the tuberculin test convert to positive. In the situation where a suckling child cannot be separated from a tuberculous mother because of the risk of malnutrition or for emotional reasons, it may be justified to give the infant isoniazid until the mother is considered non-infectious; if the tuberculin test becomes positive then isoniazid should be continued; if negative, then BCG should be given [33,307,308].

### Secondary chemoprophylaxis

The recommended dose of isoniazid for chemoprophylaxis is 300 mg daily for adults and 5 mg/kg up to a maximum of 300 mg in children, with a total duration of therapy of 1 year. The current American recommendations for secondary chemoprophylaxis and the relevant contraindications are outlined in Table 16.9 [296,309]. Needless to say, there are differences in the fervour with which these recommendations are applied and these are discussed below.

The first group for whom chemoprophylaxis is recommended includes household and other close contacts of cases of tuberculosis. If the contact procedure outlined

above is followed, isoniazid chemoprophylaxis is not required for tuberculin-negative contacts in this situation. Tuberculin-positive children are likely to have been recently infected and qualify for chemoprophylaxis. Tuberculin-positive adults are common in contact clinic populations, particularly the middle-aged [168]; in the UK at least, chest X-ray surveillance of these individuals for 1 year is recommended rather than chemoprophylaxis [33], since the majority of positive tuberculin tests in this category represent remote rather than recent infection. This avoids unnecessary exposure of individuals to the risks of isoniazid therapy (see below) while ensuring that tuberculous disease that develops is detected. Chemoprophylaxis (or even combination chemotherapy) is essential for contacts who are tuberculin skin-test converters, although in the older age groups apparent conversion may simply be a manifestation of the booster phenomenon.

The second group comprise tuberculin skin-test reactors with an abnormal chest film suggestive of inactive tuberculous disease. In the studies by the United States Public Health Service, the reduction in tuberculous morbidity in this category by isoniazid chemoprophylaxis was slight [123]. In a recent study of 27 830 20–65-year-old individuals with well-delineated radiographic lesions of probable tuberculous origin that had been stable for 1 year [310,311] the following observations were made: 3 months of isoniazid produced only a small reduction in tuberculosis compared with placebo; 6 months of isoniazid produced a 65% reduction in cases of tuberculosis; 1 year of isoniazid produced a 75% reduction in cases of tuberculosis and in those with proven good compliance for 1 year on isoniazid there was a 93% reduction in cases. Hepatitis developed in 0.46% of the treated group compared with 0.1% of the control group, with fatalities only occurring in those who took isoniazid after hepatitis developed. At least one worker questions the value of this kind of intervention [312], feeling that to halve the number of cases developing is simply not worth while viewed against the numbers who have to be treated to achieve this effect. The author's view is that individuals in this category should not receive isoniazid but should be advised to seek medical advice if they develop symptoms suggestive of tuberculosis.

The third category of patients with positive tuberculin tests in special clinical situations includes those receiving steroid or immunosuppressive therapy, those with blood and reticuloendothelial diseases such as leukaemia and Hodgkin's disease, those with diabetes mellitus, silicosis or renal transplants and those with the surgical interventions of gastrectomy or ileal bypass. One reviewer deems chemoprophylaxis unnecessary for patients receiving moderate doses of long-term corticosteroids (such as used in asthma) for respiratory disease [313]. Whether or not all of these patients receive chemoprophylaxis, a high index of suspicion of the development of tuberculous disease must be maintained throughout.

**Table 16.9** Current American recommendations for secondary chemoprophylaxis with isoniazid. (From American Thoracic Society [310].)

Indications	Contraindications
Household members, other close contacts of newly diagnosed patients and newly infected persons	Progressive tuberculous disease (combination chemotherapy required)
Positive tuberculin skin-test reactors with an abnormal but inactive chest X-ray	Adequate course of isoniazid previously completed
Positive tuberculin skin-test reactors with special clinical situations	Severe adverse reaction to isoniazid previously
Other positive tuberculin skin-test reactors up to age 35	Previous isoniazid-associated hepatic injury, acute liver disease

The fourth category recommended for chemoprophylaxis, tuberculin-positive skin-test reactors under the age of 35, is the most contentious. Treating 1000 symptomless reactors aged 35 for 12 months with isoniazid as recommended [219] would prevent 23 cases of tuberculosis or one case every 2 years [312]. An American analysis has suggested that the risk of such individuals developing active tuberculosis over 20 years is 0.56–1.3%, whereas the risk of isoniazid-induced hepatitis is 0.3–1.1% [314]. Isoniazid could therefore prevent 108–109 cases per 100 000 over 20 years but there would be 300–1100 cases of hepatitis as a consequence of the treatment. More recently, the conclusion that you can 'take it or leave it' has been arrived at [315], although individual authorities continue to promote isoniazid chemoprophylaxis in the under 35 age group most strongly [316,317] as part of the campaign to eliminate tuberculosis [318]. That chemoprophylaxis fails in this respect is known and the reasons for failure have been analysed but are not immediately amenable to solution [319]. Some therefore disagree with the recommendations of the American Thoracic Society and the Centers for Disease Control [154,219].

The risk of hepatitis from isoniazid therapy is small but real. In a trial in the USA there were eight deaths among 14 000 participants. The likelihood of toxicity increased with age and alcohol intake and was particularly high among Orientals [320]. In the USA, the reports of deaths due to isoniazid-associated hepatitis that continue to appear [321,322] have led to a cogent and reasoned pronouncement from an experienced physician that the time to promote isoniazid chemoprophylaxis as part of the programme for the elimination of tuberculosis is long since past [323].

The debate about when and where to implement chemoprophylaxis will continue. There is no doubt that in all categories currently recommended for chemoprophylaxis such intervention is effective, albeit at low levels, in reducing the subsequent numbers of active cases of tuberculosis. The difficulty is that so many healthy people have to be treated to prevent so few cases, especially with a disease eminently curable by current chemotherapy should it develop. The contribution to the public health in preventing transmission of disease is not known but is unlikely to be large. If chemoprophylaxis were to be restricted to those likely to have been recently infected, e.g. tuberculin-positive contacts of highly infectious cases, and all other tuberculin-positive reactors advised to present for chest radiography should symptoms develop, then it seems unlikely that the pattern of active disease in the community would differ from that seen now. Unnecessary isoniazid consumption would certainly decline dramatically.

Those infected with HIV and with positive tuberculin tests fit the third category of qualifiers for chemoprophylaxis but merit separate comment.

There is now good evidence that those who are dually infected with tuberculosis and HIV have a 5–10% per annum chance of developing tuberculosis [324,325]. Whether the tuberculosis is due to reinfection or reactivation [326] is not relevant since chemoprophylaxis of all such individuals who have greater than 5 mm induration to 5 TU has been shown to be effective in preventing the development of tuberculous disease [327], and is now recommended by the International Union Against Tuberculosis and Lung Disease [328].

## Antituberculosis campaign

### Developed countries

In economically developed countries the aim should be the eradication of tuberculosis [329]. In summary, the following measures should be employed.

- 1 Control of infection from cows' milk by pasteurization and tuberculin testing of herds.
- 2 Effective treatment of all patients with disease, especially infectious individuals.
- 3 Identification of all infectious or potentially infectious individuals, mainly by radiography.
- 4 BCG vaccination, although as discussed above this may eventually make an insignificant contribution.

Tuberculosis should be continuously monitored on a national level and periodic assessment of the distribution of disease in different community groups by age, sex and ethnic origin is of value in ensuring that appropriate progress is being made and for redirecting, as required, appropriate control measures [330]. Defects in notification practices [107,331,332] and provision of clinical services [333,334] need to be remedied.

### Developing countries

Where limitation of money and staff is present the main emphasis should be placed on the following.

- 1 BCG vaccination at birth or as early as possible with revaccination in later childhood.
- 2 Case finding, with the emphasis being placed on the detection of highly infectious cases by the application of inexpensive direct sputum smear examination to symptom groups.
- 3 Chemotherapy: standard short-course directly observed chemotherapy is now recommended by WHO throughout the developing world [335], although it has been employed for many years in some countries, e.g. Tanzania [336]. The potential for the development and dissemination of multidrug-resistant strains of tuberculosis in such a scenario, where chemotherapy may be abused, is avoidable if the national tuberculosis programme is organized efficiently [337].

# PULMONARY TUBERCULOSIS: CLINICAL FEATURES

A. GORDON LEITCH

This chapter is principally concerned with describing the clinical features of primary and postprimary or reactivation pulmonary tuberculosis. Congenital, classical miliary and cryptic miliary tuberculosis are also described. Extra-pulmonary tuberculosis, including pleural tuberculosis, accounted for 21% of tuberculosis notifications in white and 53% of notifications in Indian subcontinent patients in Scotland in 1993 [1] and clinical aspects of these manifestations of tuberculous disease are given in Chapter 18. Tuberculous pleural effusion is considered in Chapter 43.

## Congenital tuberculosis

### Pathogenesis

Congenital tuberculosis is a very rare condition, with fewer than 300 cases reported in the literature [2]. Tuberculous disease in the mother is invariable but may not be clinically obvious, for example miliary disease of the endometrium. Three possible modes of infection of the fetus have been proposed: haematogenous infection via the umbilical vein or fetal aspiration/inhalation of infected amniotic fluid resulting in primary lesions in the liver or lungs respectively. To satisfy the criteria for congenital tuberculosis the disease must be bacteriologically proven and present *in utero*, at birth or within the first few days of life [3]. Recently, phage typing has been used to establish the common identity of mycobacteria isolated from both mother and infant [4,5].

### Clinical features and diagnosis

The disease is usually widespread, with multiple organ involvement, and the baby is often premature. Presentation within a few days of birth is usual, often with respiratory distress due to extensive bronchopneumonia or miliary disease. Fever, hepatosplenomegaly and lymphadenopathy are common. Obstructive jaundice due to glands in the porta hepatis may occur. Presentation may simply be as failure to thrive. Positive smears may be

obtained from gastric washings, liver, lymph node or lung biopsy [6], or from tracheal aspirates. The tuberculin test is commonly negative.

### Treatment and prognosis

Treatment should be initiated with three drugs including rifampicin in appropriate dosage (see Chapter 19). Corticosteroids may be given empirically if the baby is very ill. The prognosis is poor, with only 54% of 26 treated cases surviving in a recent study [7].

### Prevention

The only hope of preventing this rare but often fatal condition lies in the screening of high-risk groups, e.g. immigrant women, and appropriate treatment of those found to be suffering from tuberculosis [2,5,8].

## Primary pulmonary tuberculosis

The first infection with the tubercle bacillus is known as primary tuberculosis and usually includes involvement of the draining lymph nodes in addition to the initial lesion [9–11]. All lobar segments are at equal risk of being seeded by inhaled infected droplets and in 25% of cases there may be more than one primary focus [12]. Probably within days the infection spreads to regional lymph nodes, with enlargement of hilar, mediastinal or subcarinal nodes. A left-sided pulmonary focus may lead to bilateral adenopathy, whereas right-sided lesions only result in right-sided adenopathy [13]. The combination of the primary (Ghon) focus and the draining lymph nodes is known as the primary complex. All other tuberculous lesions are regarded as postprimary and are not, at least in whites, accompanied by major involvement of the draining lymph nodes.

Although primary tuberculosis was formerly relatively common in the intestine or tonsil, due to infection from milk, and may occur in various other unusual sites [14], in

the great majority of cases the route of infection is by inhalation and consequently the primary lesion is pulmonary. The pathology of primary pulmonary tuberculosis has been described in Chapter 16.

### Clinical features

The great majority of primary tuberculous infections are probably symptomless, at least in young adults and adolescents [11,15,16], the infection being overcome without the individual being aware of it. A proportion may experience a brief febrile illness at the time of tuberculin conversion that is indistinguishable from the many febrile illnesses of childhood. Most children are symptom-free and are discovered only when they are investigated as contacts of an adult case. Occasionally, typical primary tuberculosis may occur in elderly people who have lost their tuberculin sensitivity.

In most cases there are no detectable physical signs. However, in a few cases, perhaps those with more severe infection or low host resistance, the child may be unwell with loss of appetite, fretfulness and failure to gain weight. Cough is not usual but may occur, and may mimic the paroxysms of whooping cough when lymph nodes or tuberculous granulation tissue impinge on the bronchial wall [17]; wheeze may be a result of the same process. Sputum production is rare in children. Auscultation of the

chest is usually unrewarding but occasionally crepitations may be heard over an extensive primary focus. More obvious physical signs may be present if there is segmental or lobar exudation or collapse (see below).

### Radiological features

Radiological changes are found at the time of tuberculin conversion in 7–30% of young adults, being higher in those exposed to a known source of infection [15,18]. The prevalence of radiological changes in children varies in different populations: in a Nigerian series, 79% had lymphadenopathy and 68% had a parenchymal lesion [19] (Fig. 17.1); in a Canadian series, 94% had lymphadenopathy [20]. The hilar lymph node was most commonly involved but the paratracheal node was also frequently enlarged and a substantial minority had enlargement of both hilar and paratracheal nodes. Occasionally, especially in Asians, bilateral hilar adenopathy may be seen. In adults the lung component of the primary complex is usually more obvious and the nodal component may not be seen, whereas in children often only an enlarged hilar or paratracheal node is seen. There may be radiological evidence of segmental or lobar consolidation or obstructive emphysema (see below). Radiological abnormality persists in a majority 6 months after diagnosis but complete resolution is usual after 2 years [20].

In due course, usually after a year or more but rarely earlier, the lung or nodal component of the primary complex or both may calcify. Calcification may occur in the absence of any chest radiographic changes in the acute stage. In some cases the calcification may eventually disappear [21,22].

**Fig. 17.1** (a) Chest radiograph of an Asian child with primary tuberculosis showing hilar and paratracheal lymph gland enlargement. (b) Later film showing tuberculous consolidation of right upper lobe ('epituberculosis').

(b)

## Diagnosis

The clinical manifestations of primary pulmonary tuberculosis are by no means specific but the disease should always be borne in mind when there is vague ill-health, particularly if there is a history of contact with an infectious case of tuberculosis. By the time there is clinical or radiological evidence of tuberculosis the tuberculin test is usually strongly positive, a negative test making the diagnosis unlikely. The radiological changes outlined above are more helpful in diagnosis, although where there is doubt about a parenchymal lesion a trial of non-tuberculous chemotherapy may be helpful in distinguishing a simple pneumonic process from tuberculosis: simple pneumonia usually improves after 2 weeks, while a tuberculous process will be unchanged.

Sputum is rarely produced by children with primary pulmonary tuberculosis and gastric washings are more frequently obtained for mycobacterial examination [23]. Smears positive for acid-fast bacilli are uncommon and positive mycobacterial cultures can be expected in only 20–25% of cases [20]. Attempts to improve diagnostic returns by employing serological [24,25] or mycobacterial DNA amplification [26] techniques are in their infancy and cannot be recommended as routine at present.

## Complications

### Collapse/consolidation

The term 'epituberculosis', coined by Eliasberg and Neuland [27,28] to describe the development of dense homogeneous shadows in the lungs of children with tuberculosis, has now properly been abandoned. These radiological appearances are due to lobar or segmental consolidation/collapse (Fig. 17.2), are associated with enlarged tuberculous lymph nodes at the hilum and, as in Fig. 17.2, may rarely occur in elderly subjects who have lost their tuberculin sensitivity. The middle lobe is most often affected. Segmental lesions are seen in 43% of infected infants, 25% of those aged 1–10 years and 16% of those aged 11–15 years [11].

The radiographic appearances may be due to collapse, inflammatory exudation, caseous pneumonia or any combination of these three. Collapse is produced by pressure of the lymph node on the bronchus, by the spread of tuberculous granulation tissue into the bronchus with resultant stenosis or by discharge of caseous material from the lymph node through the bronchial wall [29–31]. Later the bronchial lesion may heal with residual scarring or fibrous stenosis. The available pathological evidence suggests that the commonest cause for the appearance is inflammatory exudate, either monocytic or polymorphonuclear. Epithelioid tubercles may also be present [22]. The

exudate is probably due to the discharge of caseous material into the bronchial lumen, with aspiration into a segment or lobe and a resultant exudative hypersensitivity reaction to the contained tuberculo-protein. It is not possible on purely radiological grounds to distinguish this appearance from caseous pneumonia, although the latter may be inferred from the absence of clinical illness and the later development of calcification. Actual caseous pneumonia appears to be very unusual, although small areas of caseation may occur [32].

Clinically, there is a greater likelihood of wheeze or paroxysmal cough. Dullness to percussion, diminished air entry, bronchial breathing or crepitations may be found. In infants and young children sudden asphyxia resulting in death may occur.

Treatment does not differ from that for primary tuberculosis, except that corticosteroids are utilized on the basis that a hypersensitivity reaction is often involved [33,34]. The daily dose should be equivalent to prednisolone 1–2 mg/kg and this should be continued for 4–6 weeks with a gradual reduction thereafter. Steroid therapy may need to be resumed if there is any subsequent radiological or febrile relapse. Steroid therapy may reduce the rate of residual bronchiectasis following this complication of primary pulmonary tuberculosis [33]. Rarely, surgical resection of nodes may be necessary in infants because of the threat of asphyxia.

### Bronchiectasis

Distension by mucus, caseous tissue or secondary infection beyond a bronchial stenosis may result in bronchiectasis, especially following lobar or segmental lesions [35]. The incidence is reduced by prompt chemotherapy and the use of corticosteroid drugs [33].

### Obstructive emphysema

Occasionally a bronchus is compressed in such a way that a valve action results, with air being admitted to a portion of lung on inspiration but unable to escape on expiration. This results in distension of a segment or lobe, often with depression of the horizontal fissure or diaphragm and deviation of the mediastinum on expiration. The phenomenon is best shown on a chest film taken on expiration. The condition is rare but is commoner in children under the age of 2 years [11,36]. It usually resolves with chemotherapy and may be an indication for the use of corticosteroid drugs.

### Broncholith

Calcification in a primary focus, or more commonly in a lymph node, may later be extruded into a bronchus as a 'broncholith', which may declare itself with haemoptysis.

**Fig. 17.2** Chest radiograph of 70-year-old Asian lady with primary tuberculosis showing (a) peripheral focus and enlarged right hilar nodes and (b) consolidation of right middle lobe 1 week later. The diagnosis was made following bronchial biopsy, carcinoma having been suspected originally.

Such broncholiths may be seen through the bronchoscope but are best left well alone.

### **Erythema nodosum**

Erythema nodosum has been reported to have accompanied primary tuberculous infection in 1–2% of British [15,37] and 5–15% of Scandinavian [38] cases. It is rare below the age of 7, with an increase in frequency up to

puberty. It is commoner in girls than boys at all ages and after puberty 80–90% of cases are in females [38].

Tuberculin conversion is said to precede the eruption by a few days to a few weeks in most cases, although erythema nodosum may also occur later in primary or even postprimary disease. The rash is probably a manifestation of the Arthus phenomenon, as in erythema nodosum leprosum, where local deposits of immunoglobulin, complement and soluble mycobacterial antigen have been

demonstrated [39]. The characteristic feature of erythema nodosum is the presence of tender, dusky-red slightly nodular lesions on the anterior surfaces of the legs (Fig. 17.3), although lesions are occasionally also found on the anterior surfaces of the thighs, the extensor surfaces of the forearms and rarely on the face and breasts. The nodules are usually 5–20 mm in diameter, have ill-defined margins and may become confluent. They usually resolve over a week or two, the red colour fading to purple and then brown, the brownish pigment often persisting for several weeks. Recurrent crops of lesions may occur.

The amount of systemic reaction varies greatly. Fever may precede the eruption by days or weeks and usually resolves with clearing of the lesions. Occasionally a high fever persists for several weeks in association with recurrent crops of nodules. Arthralgia is common in adults, affecting the larger joints, wrists, elbows, knees or ankles, and joints may sometimes be hot, swollen and tender, mimicking acute rheumatic fever. The erythrocyte sedimentation rate (ESR) is usually high and there may be a leucocytosis. The tuberculin test is virtually always strongly positive. A negative tuberculin test suggests a non-tuberculous cause such as sarcoidosis.

Chemotherapy for tuberculosis is of course indicated in the presence of a chest radiograph suggesting primary

Fig. 17.3 Legs of patient with erythema nodosum.

tuberculosis but should also be given if the tuberculin test is strongly positive even when the chest film is normal, as postprimary tuberculosis is more likely to develop when erythema nodosum complicates first infection. The fever and eruption usually respond well to chemotherapy and failure to respond suggests that the diagnosis should be reviewed. The systemic manifestations of erythema nodosum are also usually adequately controlled with non-steroidal anti-inflammatory drugs. Occasionally corticosteroids may be indicated.

### Phlyctenular conjunctivitis

This condition also reflects hypersensitivity to the tubercle bacillus but, unlike erythema nodosum, is not necessarily confined to the first weeks of infection. It usually occurs within the first year [40], is most often seen in children and is said to be commoner in those with poor social backgrounds and in non-European communities in Africa and America [11].

The lesion is usually seen in one eye but may occur in both either simultaneously or successively. It begins with irritation, lacrimation or photophobia. The characteristic finding is of a small 1–3 mm shiny yellowish or grey bleb at the limbus, with a sheaf of dilated vessels running out towards it from the edge of the conjunctival sac. The reaction subsides in a week or so but multiple crops may occur, either successively or at intervals.

Any underlying tuberculosis should be treated by chemotherapy. Locally the pupil is dilated with atropine, and 1% hydrocortisone drops rapidly relieve the symptoms. If attacks continue to occur in spite of chemotherapy, desensitization to tuberculin may be effective [41].

### Pleural effusion

Pleural effusion may sometimes accompany primary pulmonary tuberculosis in children under the age of puberty [19,20]. Such effusions are usually small and transient, resolving with chemotherapy. Larger effusions are commoner after puberty and are discussed in Chapter 43.

### Miliary tuberculosis

Miliary tuberculosis is produced by acute dissemination of tubercle bacilli via the bloodstream. The term 'miliary' derives from the radiographic picture of diffuse, discrete, nodular shadows about the size of a millet seed (2 mm) that are characteristic of the classical disease. Although the overt case is relatively easily diagnosed, cryptic forms are not at all uncommon. In communities where tuberculosis is now greatly decreased, these cryptic forms in older people contribute an important proportion of cases of miliary tuberculosis and are sometimes diagnosed only at

postmortem. In one report serious miliary disease was not recognized until postmortem in 15 of 21 patients, most of whom were over 70 [42]. Other studies have emphasized failure to consider the diagnosis with resultant delays in initiating therapy and death [43–47]. In Edinburgh in the 1980s the mean age of all patients with miliary tuberculosis was 74 years and 40% had cryptic miliary disease [46]. Since the disease is almost always fatal without adequate treatment and recovery is the rule if proper chemotherapy is given, the importance of making the diagnosis needs no emphasis.

### Pathogenesis

When tuberculosis was widespread in the community the majority of cases of miliary tuberculosis closely followed the primary tuberculous infection in young children, more than one-third in one series being aged less than 3 years [48]. If the initial infection is overwhelming or the patient's defences are poor due to malnutrition, intercurrent disease or corticosteroid or immunosuppressive drug therapy, then the haematogenous phase of the primary infection may give rise to acute miliary tuberculosis. Seeding of bacilli into vessel walls may cause a caseous vasculitis of the intima, with subsequent discharge of bacilli into the bloodstream. Such lesions are said to be commoner in the large veins and the thoracic duct but less so in the arterial system, aorta or endocardium [49]. Miliary dissemination may also follow recrudescence of an old primary lesion, which may discharge itself into a vessel wall. Vascular invasion presumably also occurs from other active postprimary lesions, thus explaining the now relatively more frequent occurrence of miliary tuberculosis in the middle-aged and elderly.

### Pathology

In the commonest or classical form of miliary tuberculosis, the millet seed-sized lesions consist of clumps of epithelioid cells, lymphocytes and Langhans' giant cells with or without central caseation in which acid-fast bacilli are seen. The distribution of the lesions in the body is variable but the lungs are virtually always affected, sometimes only microscopically. Involvement of other organs varies from case to case. Lesions may occur in any of the serous sacs with resultant effusions.

A variant pathological type known as 'non-reactive' is almost only seen in adult cases and in immunosuppressed children. Here the lesions are mainly necrotic, with no obvious tuberculous histology, and are teeming with tubercle bacilli. The spleen and liver may be enlarged and studded with irregular necrotic foci, usually less than 1 cm in diameter or only visible microscopically. Any organ may be affected.

## Clinical features

### Acute or classical miliary tuberculosis

The disease is most common in infants and young children [50]. In children, the onset may be associated with an acute or subacute febrile illness [11,48,51] but often, especially in adults [44,52–54], the onset is insidious with gradual development of vague ill-health, malaise, anorexia, weight loss and fever. Cough, breathlessness, haemoptysis and night sweats are less common. Headache as a feature suggests associated tuberculous meningitis, which is found in an appreciable proportion of cases.

Apart from fever there may be no physical signs; in particular, the chest is frequently normal on auscultation, although crepitations may develop in the later stages. Hepatomegaly, nuchal rigidity, lymphadenopathy and splenomegaly may be found in a proportion of cases [52,53,55–57]. Choroidal tubercles are found in over 90% of children with miliary tuberculosis but less commonly in adults [48,58]. A search of the fundus is difficult in an irritable ill child and if it is important from a diagnostic point of view the pupils should be dilated and the child given an anaesthetic [58]. The lesions are usually less than one-quarter of the diameter of the optic disc. They are initially yellowish, a little shiny and give the impression of being slightly raised. Later they become flatter and may be very white in the centre and ultimately pigmented. There may be only one or two lesions or they may be very numerous. Miliary lesions of the skin are very occasionally seen and may take the form of macules, papules, vesicles or purpuric lesions [59].

### Cryptic miliary or disseminated tuberculosis

The cryptic form of disseminated disease is increasingly being seen in the elderly [46], where it may be difficult to diagnose since the chest film may be normal, choroidal tubercles are absent and the tuberculin test may be negative. The most common presentation [60,61] is with the insidious onset of weight loss, malaise and a fever of unknown origin. Anaemia is usual and the ESR is often elevated. A variety of blood dyscrasias, including leucopenia, pancytopenia, aplastic anaemia, leukaemoid reactions leucoerythroblastic anaemia and polycythaemia, have been seen [62–71]. The liver function tests are commonly disturbed, with elevation of transaminases and alkaline phosphatase. Hyponatraemia and hypokalaemia are also commonly seen [72,73].

### Radiology

It is important to recognize that the chest radiograph may be quite normal in the presence of miliary tuberculosis,

**Fig. 17.4** (a) Chest radiograph showing miliary tuberculosis. (b) Magnified view of the lung periphery in miliary tuberculosis.

since the lesions are too small to be seen. When abnormal shadows are present they are usually fairly evenly distributed and may vary from faint shadows 1–2 mm in diameter to large dense shadows up to 5 or 10 mm. Usually the shadows are all a similar size (Fig. 17.4) but, as the disease progresses, larger coalescent shadows may develop. Evidence of a primary tuberculous complex, complicating segmental lesion or a postprimary lesion may be seen. Bilateral pleural effusion may occur. Rarely the appearance may be reticular, with a network of thin dense lines that has been shown to be due to lymphatic involvement, hence its description as lymphangitis reticularis tuberculosa [74]. The author has seen an 80-year-old patient die from presumed bronchopneumonia with a radiograph confidently reported as showing diffuse interstitial pulmonary fibrosis; in fact, she had non-reactive miliary tuberculosis. Following initiation of treatment the radiographic lesions clear slowly, taking up to 3–4 months on average but sometimes longer. There may be residual miliary calcification.

### Diagnosis

Diagnosis in the classical case with a febrile onset, miliary shadows on the chest film and perhaps with choroidal tubercles and an enlarged spleen is not difficult. The tuberculin test may be positive but this is not invariable and direct smear of fluid obtained by gastric lavage or

sputum if present may confirm the diagnosis. If necessary, transtracheal aspirates or fiberoptic bronchoscopic biopsy or lavage specimens can be obtained for microbiological examination [75]. The differential diagnosis of fever with miliary shadows includes bronchopneumonia due to haemolytic *Streptococcus*, *Staphylococcus* and *Mycoplasma pneumoniae*. If reasonable doubt exists, then the patient should be treated for both conditions until a firm diagnosis can be reached. Non-mycobacterial pneumonia clears much more rapidly than miliary tuberculosis. There has been a report of disseminated histoplasmosis simulating miliary tuberculosis, even to the extent of exhibiting choroidal lesions [76].

If there is no microbiological evidence of tuberculosis in an ill patient with a pyrexia of unknown origin, even if the chest film is normal and the tuberculin test negative, a therapeutic trial of specific antituberculosis chemotherapy is indicated and this should be started whether or not biopsies of liver and bone marrow have been taken for culture of acid-fast bacilli [77,78]. In proven cases, such biopsies will be positive on culture in the majority of patients [61]. While the cultures are awaited, the patient should be treated with isoniazid plus ethambutol in standard dosage, since these drugs act specifically on *Mycobacterium tuberculosis*, and the effect on the pyrexia and the haematological and biochemical abnormalities monitored. Improvement is usually seen within a few days (Fig. 17.5), after which standard chemotherapy should be introduced. Failure of the pyrexia to respond within 2 weeks makes the diagnosis of tuberculosis unlikely but not impossible. No patients with pyrexia of unknown origin, particularly those who are elderly,

**Fig. 17.5** Cryptic miliary tuberculosis: temperature chart of a 70-year-old man presenting with pyrexia and normocytic anaemia but a negative tuberculin test and normal chest radiograph. The pyrexia and anaemia responded to treatment with para-aminosalicylic acid and isoniazid.

immunosuppressed or immigrants, should be allowed to deteriorate and die undiagnosed without having such a trial of antituberculosis therapy.

## Complications

### Adult respiratory distress syndrome

Miliary tuberculosis may present with all the features of the adult respiratory distress syndrome or the syndrome may even develop after treatment has been initiated [79,80]. Therapy should be directed to both conditions.

### Immune complex nephritis

Immune complex nephritis complicating miliary tuberculosis has been described [81].

## Postprimary pulmonary tuberculosis

Postprimary pulmonary tuberculosis is by far the most important type of tuberculosis, partly because it is much the most frequent and partly because smear-positive sputum is the main source of infection responsible for the persistence of disease in the community. The pathology and pathogenesis are considered in detail in Chapter 16.

### Pathogenesis

Postprimary pulmonary tuberculosis may arise in one of three ways: (i) direct progression of a primary lesion; (ii) reactivation of a quiescent primary or postprimary lesion; and (iii) exogenous reinfection.

### Progression of the primary lesion

This is most likely to occur if the primary infection has occurred around the time of puberty [82,83]. This is true particularly for those of European stock, although progressive primary lesions can occur before puberty in Africans and Asians.

### Reactivation of the primary or postprimary lesion

This can occur at any time in a patient's life. The original lesion need not necessarily be visible radiographically and

the only evidence that it has occurred may be a positive skin test. It is probable that the great majority of middle-aged and elderly men who develop postprimary pulmonary tuberculosis do so as a result of a reactivation of lesions contracted many years previously. Waning of an individual's defences at any time of life may result in the development of postprimary pulmonary tuberculosis. Examples of predisposing factors are given below.

### Nutrition

Malnutrition is believed to predispose to tuberculosis. Evidence from the two world wars is suggestive: during the blockade of Germany in 1914–18, mortality from tuberculosis rose more in Saxon and Russian industrial towns, where food shortage was severe, than in rural Bavaria; also in the last year of the Second World War, there was an enormous rise in mortality in the occupied area of The Netherlands where the population was starving. One of the most impressive pieces of evidence regarding the effect of nutrition was the sudden increase in mortality due to tuberculosis in French prisoners of war in Germany after the cessation of Red Cross food parcels in 1944, following the invasion of France by the Allies.

### Housing/homelessness

Poor housing conditions with overcrowding, such as still exist in many common lodging houses [84,85], may contribute to disease, although other factors such as nutrition, smoking, alcohol consumption and human immunodeficiency virus (HIV) infection are also important in this context. Tuberculosis in this population may be due to reactivation disease in one individual and reinfection or new infection in others [86,87]. Incidence rates may be several hundred times higher than in the population at large [87].

### Occupation

Workers in occupations giving rise to pulmonary silicosis, such as masons, quarry workers, knife-grinders and coal-miners, have a greater risk of developing tuberculosis [88]. Silica appears to have a specific effect in lowering resistance to the disease, perhaps through a toxic effect on pulmonary macrophages [89]. Tuberculosis is commoner

among the health-service professions due to an increased risk of exposure to the disease [90,91].

### *Alcoholism*

Tuberculosis is common in alcoholics, contributory factors probably being malnutrition, adverse social factors and a direct effect of alcohol on host defences [92,93].

### *HIV infection*

The association of HIV infection with tuberculous disease is now well recognized and is described in detail in Chapter 16.

### *Cigarette smoking*

In patients of both sexes over the age of 30 suffering from pulmonary tuberculosis it has been shown that there is a highly significant deficiency of non-smokers and light smokers and an excess of moderate and heavy smokers compared with controls of the same age suffering from other diseases [94,95]. Mortality from pulmonary tuberculosis among doctors has been shown to increase significantly with the number of cigarettes smoked [96], and a similar effect has been found among US veterans [97]. These findings may be related to the higher alcohol consumption of smokers [92].

### *Steroid and other immunosuppressive drugs*

Reactivation of tuberculosis may occur in patients receiving corticosteroid or other immunosuppressive drugs for the treatment of disease or for the suppression of transplant rejection. The disease being treated may also contribute to such reactivation [98].

### *Other diseases*

Diseases associated with impaired cellular immunity, such as Hodgkin's disease, leukaemia, lymphoma and AIDS, may predispose to reactivation [99–103]. Gastrectomy probably predisposes to tuberculosis, particularly in patients with low weight/height ratios or malabsorption syndrome [104]. Diabetes mellitus may predispose to tuberculosis and also lead to a significant increase in cavity and smear-positive disease [105,106].

### *Exogenous reinfection*

Most tuberculin-positive individuals have sufficient immunity to control an episode of reinfection with tubercle bacilli and prevent the development of disease. However, such reinfection may lead to disease (as has been confirmed by DNA fingerprinting studies [107,108]),

although this is probably an uncommon cause of disease in developed countries. Disease from reinfection may be more common in populations with a high prevalence of tuberculosis, as was once the case with Eskimos [109]. Most cases of pulmonary tuberculosis arise either from a progressive primary lesion (in young people) or from reactivation of a dormant primary or postprimary lesion (in the middle-aged or elderly) [110].

### **Clinical features**

In the developed countries, the majority of patients with postprimary pulmonary tuberculosis are middle-aged or elderly, the trend towards increasing age (and also increasing numbers of alcoholics) being significant in comparison with 20 years ago [111]. In Scotland in 1993, 64% of white patients with tuberculosis were aged over 55 years; in comparison, 85% of Asian patients were under 55 years [1]. In developing countries, the age distribution is strikingly different (Fig. 17.6), with a preponderance of young and young middle-aged patients [112].

### **Symptoms**

Active disease may be present with no symptoms at all, while mild debility may be so gradual in onset that patients do not notice it and may feel so much better after chemotherapy that only subsequently do they realize they were unwell. There is little that is specific about the symptoms of tuberculosis but one of the points in the history that may make tuberculosis a possibility is the gradual onset of symptoms over weeks and months. Clearly,

Fig. 17.6 Age and sex distribution in the National Tuberculosis and Leprosy Programme in Tanzania.

middle-aged or elderly patients with carcinoma of bronchus may give a similar history.

Many patients with tuberculosis present with general symptoms, such as tiredness, malaise, loss of appetite, weakness or loss of weight. In advanced cases, febrile symptoms may be reported and night sweats, a classic symptom of tuberculosis, are still commonly admitted by patients with extensive disease. Symptoms are most frequently related to the respiratory system, with cough as the outstanding manifestation. Cough is such a common finding among cigarette smokers that many patients ignore it; however, anyone who develops a cough, or an exacerbation of cough, persisting for more than 3 weeks, even if attributed entirely to cigarette smoking, should have a chest radiograph. Sputum may be mucoid, purulent or blood-stained. Many patients simply admit to cough productive of mucoid or purulent sputum, again often attributed to chronic bronchitis. Haemoptysis is a classic symptom of pulmonary tuberculosis and may vary from mere blood-staining of the sputum to the rarer occurrence of sudden eruption of half a litre or more of blood, occasionally immediately fatal. Massive haemoptysis is usually due to erosion of a bronchial artery, which bleeds at systemic pressure. Chest pain is common and may vary from a dull ache or tightness to pleuritic pain. Coughing may result in 'soreness' of the chest and occasionally a cough fracture. With extensive pulmonary disease, breathlessness may be a feature and endobronchial tuberculosis, although uncommon, may result in localized wheeze [113–118].

It is not uncommon for a patient to present with a history of recurrent colds for a number of months. On close questioning these usually prove to be exacerbations of cough. Patients may occasionally present with an apparent acute pneumonia, the diagnosis of tuberculosis only being made on routine examination of sputum or because of failure of clinical or radiological resolution with broad-spectrum antibiotics. Finally, amenorrhoea may be a presenting symptom, usually in severe tuberculosis.

In summary, the following are the common presentations:

- 1 symptom-free, discovered on routine radiography;
- 2 persistent cough with or without sputum;
- 3 general malaise;
- 4 weight loss;
- 5 recurrent colds;
- 6 pneumonia which proves to be tuberculous;
- 7 haemoptysis.

### Physical signs

There may be no physical signs in pulmonary tuberculosis even with relatively advanced disease, although there may be pallor, a hectic flush or cachexia in severe disease.

In the UK, most patients are afebrile at the time of diagnosis but with more extensive disease there may be a varying degree of fever and the respiration rate may be increased with advanced disease. Finger clubbing is unusual even in chronic disease and in the UK suggests another diagnosis, in particular carcinoma of the bronchus. Severe clubbing has been reported in Africa in association with advanced disease [119].

In the chest there may be no physical signs whatever in spite of extensive radiological changes. The most common early abnormality consists of post-tussive crepitations in the upper zones or apices. With advanced or pneumonic disease there may be signs of consolidation. In chronic disease, deviation of the trachea may occur due to fibrosis. The classical physical signs of a cavity are seldom found even when large cavities are evident on the chest film. Localized wheezes may occasionally be heard if the patient has severe endobronchial tuberculosis.

In general, examination of the chest contributes relatively little to the diagnosis or assessment of postprimary tuberculosis. Sputum examination and chest radiography are much more important. However, it is essential to conduct a general examination of the patient as there may be additional tuberculous lesions outside the chest.

### Radiology

A normal chest film almost, although not completely, excludes pulmonary tuberculosis. There are two provisos. First, it has been shown in a number of studies that small radiological lesions are easily missed [120–123]. Such observer error may be reduced by double reading by two independent observers or even by the same observer on two separate occasions. Second, it is possible for a patient to have localized postprimary endobronchial tuberculosis with a positive sputum and a normal chest film [118].

### Appearances suggestive of tuberculosis

It is seldom possible to make a completely confident diagnosis of pulmonary tuberculosis on radiological grounds alone, as almost all the manifestations of tuberculosis can be mimicked by other diseases. The following characteristics of a chest radiograph favour the diagnosis of tuberculosis:

- 1 opacities mainly in the upper zone(s);
- 2 patchy or nodular opacities;
- 3 presence of a cavity or cavities;
- 4 presence of calcification;
- 5 bilateral opacities especially if in upper zones;
- 6 opacities that persist after several weeks (and thus are less likely due to acute pneumonia).

In appropriate areas, such as North America, all these appearances can be found in histoplasmosis and most of them in coccidioidomycosis (see Chapter 21).

### Characteristic radiographic appearances

Pulmonary tuberculosis can mimic almost all other pulmonary diseases in much the same way that syphilis mimics most neurological diseases.

Soft confluent shadows alone suggest an exudative process and may be difficult to distinguish initially from a simple pneumonia. There may be different foci in the lungs. Linear shadows, especially if they produce distortion of fissures, trachea, mediastinum or diaphragm, suggest fibrosis; bilateral upper zone fibrotic shadows, with shrinkage of the upper lobes and elevation of the pulmonary hila, is a common picture (Fig. 17.7). The presence of calcification suggests healed disease, although activity is impossible to determine solely on radiographic grounds, in many cases reactivation occurring on a background of an old calcified lesion. Linear and soft shadows may coexist. Tuberculous disease is usually located in the posterior or apical segments of the upper lobe but, exceptionally, may be restricted to the anterior segment of the upper lobe [124].

Cavitation results from a valvular process in a draining bronchus. Cavities in a mass of caseous material may initially have irregular walls that later become smoother and thinner as caseous material is coughed up or absorbed (Fig. 17.8). A cavity may become 'blocked' and fill with purulent or caseous material, so-called tuberculoma (Fig. 17.9), but with effective chemotherapy such lesions

usually resolve satisfactorily [125]. However, cavities may persist permanently even after effective chemotherapy and eventually be colonized by *Aspergillus* to produce an aspergilloma (see later). Tuberculous cavities may be differentiated from non-tuberculous cavities on the basis of a longer history of illness and the presence around them and in other parts of the lungs of patchy or nodular infiltrates and atelectasis. Non-tuberculous cavities more often have putrid sputum, associated leucocytosis and fluid levels [126]. CT may sometimes be used to confirm the presence of cavities and may also be useful in detecting calcification in a suspicious lesion; this, and the presence of satellite lesions on such tomographic studies, make the diagnosis of tuberculosis more likely.

Bronchiectasis may be suggested by elongated translucent areas in the upper zones and can be confirmed by bronchography, although this does not affect management. If such a bronchus becomes blocked and fills with caseous material, a so-called 'bronchial cold abscess' may form and show as a solid-looking elongated dense shadow, sometimes scalloped.

Enlargement of hilar or paratracheal lymph nodes is unusual in European adults but more frequent in Asians or Africans [127]. The lymphadenopathy and pyrexia in the presence of a positive tuberculin test may be the only manifestations of tuberculous disease. Tuberculosis limited to the lower zones of the lung is uncommon but does occur [128,129].

**Fig. 17.7** Chest radiograph showing bilateral apical fibrosis with calcification and upper lobe shrinkage with elevation of the hila.

**Fig. 17.8** Extensive bilateral tuberculosis with cavity formation at right apex.

### **Radiological classification of disease extent**

For clinical and research purposes the classification of the National Tuberculosis Association of the USA has proved useful [130].

#### ***Minimal***

Minimal lesions include those that are of slight to moderate density but which do not contain demonstrable cavitation. They may involve a small part of one or both lungs, but the total extent, regardless of distribution, should not exceed the volume of lung on one side that occupies the space above the second chondrosternal junction and the spine of the fourth or the body of the fifth thoracic vertebra.

#### ***Moderately advanced***

Moderately advanced lesions may be present in one or both lungs, but the total extent should not exceed the following limits: disseminated lesions of slight to moderate density that may extend throughout the total volume of one lung or the equivalent in both lungs; dense and confluent lesions limited in extent to one-third the volume

of one lung; total diameter of cavitation, if present, must be less than 4 cm.

#### ***Far advanced***

Lesions more extensive than moderately advanced.

### **Other investigations**

#### **Sputum examination**

Sputum examination is of great value in making the diagnosis of pulmonary tuberculosis and in following the patient's response to treatment. If sputum production is difficult, it may be induced by inhalation of nebulized saline. Sputum should first be examined by direct smear using the Ziehl–Nielsen stain. The fluorescence method allows large numbers of specimens to be examined rapidly [131]. Quantitative grading of smears is of value in following progress especially in research [132,133]. Sputum smear examination is usually positive in advanced disease but may be negative in less advanced disease. Sputum smear examination had a sensitivity of about 50% and a specificity of greater than 99% in two reported studies, with a positive predictive value of

**Fig. 17.9** Chest radiograph showing large tuberculoma in right mid-zone, originally thought to be a coincidental carcinoma in patients with extensive upper lobe tuberculosis.

91–98.5% [134,135]. In one study, smears were positive in 52% of patients with cavitating disease but in only 32% with non-cavitating disease [135]; the same study found that 96% of patients with cavitating disease had positive cultures compared with only 70% with local infiltrates. In Edinburgh in 1993, 60% of notified cases of postprimary pulmonary tuberculosis were bacteriologically positive. Comparable figures for European countries are shown in Table 17.1. The considerable variations between European countries for positive mycobacteriology findings has led to recommendations for uniform case definitions and standards of reporting to facilitate international comparisons [137].

Growth is visible on culture only after 3–8 weeks. Guinea-pig inoculation of the sputum is probably more sensitive than a single culture but is now very rarely carried out since multiple cultures are as sensitive as inoculation. Rapid diagnosis is now possible within 2–6 days using a radiometric culture system, the Bactec system [138]. This is particularly valuable for early determination of the resistance characteristics of mycobacteria. In any patient in whom the diagnosis is in doubt,

**Table 17.1** Proportion of cases of pulmonary tuberculosis bacteriologically confirmed in Europe in 1983. (From Horne [136].)

Country	Percentage positive
Belgium	59
Czechoslovakia	55
Denmark	73
England and Wales	56

repeated smear and culture examinations should be carried out.

Sputum is sometimes both smear and culture negative even when there are well-marked radiological opacities, symptoms and a subsequent appropriate response to anti-tuberculosis chemotherapy. Such patients may still demonstrate radiographic resolution following antituberculosis chemotherapy consistent with the diagnosis [139]. Direct smear is occasionally negative even in a patient with far advanced disease and, rarely, cultures are also negative. By contrast, it must be remembered that an unexpected positive smear or culture in a patient whose clinical characteristics do not otherwise suggest tuberculosis may be due to a laboratory error (such as a mistake about a name or contamination); alternatively, a neoplastic or infectious process in the lung may have eroded an old tuberculous focus. A single unexpected positive in an inappropriate clinical situation should not be given great weight unless repeated. The possibility of opportunistic mycobacterial infection (see Chapter 20) should be borne in mind. Sputum examination, like all other examinations, must be considered in the total clinical context.

Following the initiation of modern chemotherapy (Chapter 19) sputum cultures become negative most quickly in smear-negative culture-positive disease, less quickly in direct smear-positive cases and least quickly in direct smear-positive cases with far advanced disease, where 8% still have positive cultures after 3 months of therapy [140]. With modern chemotherapy, it is not unusual for organisms to be coughed up and visible on smears but not to grow in culture; this smear-positive culture-negative phenomenon has been observed in 20% of cases for a few weeks after the start of therapy [140].

#### **Bacteriological examination of samples other than sputum**

##### ***Gastric aspirate***

Sputum, especially if not abundant, is frequently swallowed rather than coughed up. In such a situation aspiration of early-morning gastric secretions may reveal acid-fast bacilli on staining [141,142]. The secretions should also be cultured.

##### ***Laryngeal swabs***

Laryngeal swabs are an alternative to gastric aspiration and are simpler to perform and less uncomfortable for the patient [142,143]. The operator should be gowned and masked and the swabs taken in pairs. The first swab usually makes the patient cough and the second often collects the better specimen.

##### ***Fibreoptic bronchoscopic specimens***

Where the conventional methods of obtaining bacterial confirmation of suspected tuberculosis have failed, flexible fibreoptic bronchoscopy may be utilized to provide direct smear or culture-positive specimens from bronchial washings, bronchial brushings or trans-bronchial biopsies [130,144–147].

##### ***Transtracheal aspirate***

This procedure may also yield positive specimens when sputa are negative [148] but the author considers bronchoscopic specimens more productive of results.

##### ***Fine-needle aspiration biopsy***

Where this procedure is being employed to obtain cytology from a doubtful lesion in the lung, if tuberculosis is a possibility then both direct smear and culture of the specimen may yield positive results [149].

##### ***Mediastinoscopy***

Occasionally, mediastinoscopy may be necessary in patients (usually Asians) to provide mediastinal lymph node specimens for pathological and bacteriological examination [150].

#### ***Newer diagnostic techniques***

##### ***Serological diagnosis of tuberculosis***

Serodiagnosis of tuberculosis has been under investigation for some years [151–157], although there is no evidence that serological diagnosis provides any more diagnostic information than can be made available from conventional microbiological investigation. Serodiagnosis using enzyme-linked immunosorbent assay does not add to diagnosis in cases where sputum smears are available [155] and results so far in patients with negative sputum smears have been disappointing [153].

##### ***Polymerase chain reaction***

Diagnostic polymerase chain reaction (PCR) is theoretically capable of detecting a single organism in a specimen of sputum [151,158]. To date its role in clinical practice is not clear. For example, one study reported sensitivity and specificity for sputum PCR of 92 and 99%, although there were only 12 cases of active tuberculosis among the 108 patients studied and PCR failed to detect the one patient with smear-negative culture-positive tuberculosis [159]. In contrast, Walker *et al.* [160] found positive PCR tests even in patients with a past history of tuberculosis or of

tuberculosis exposure. It would seem that this technique still needs evaluation and at the present market prices it is unlikely to displace conventional microbiology.

## Haematology and biochemistry

### *White blood cell count*

In general, a normal total white blood count in the presence of extensive pulmonary shadowing on a chest radiograph favours a diagnosis of tuberculosis (or atypical pneumonia) rather than acute pneumonia or lung abscess. Exceptions to this rule are frequent.

### *Haemoglobin*

A normochromic normocytic anaemia is common in pulmonary tuberculosis but the more bizarre blood dyscrasias characteristic of miliary tuberculosis are unusual and, if present, most likely imply severe disease with cryptic miliary spread.

### *Liver function tests*

It is not uncommon to find abnormalities of liver function tests in moderate or advanced tuberculosis. Since many of the chemotherapeutic agents are hepatotoxic, it is therefore important to determine baseline values for liver function before initiating chemotherapy.

### **Tuberculin testing**

Most patients with postprimary pulmonary tuberculosis have a strongly positive tuberculin test (see Chapter 16).

### **Gallium scanning**

Gallium scanning [161] is of no value in the diagnosis of tuberculosis.

### **Assessment of activity**

Abnormal chest radiographic opacities due to pulmonary tuberculosis are very common, especially in older people in developed countries and at all ages in developing countries. It is often difficult to decide whether a particular lesion should be treated or whether it merits further follow-up to assess activity. The following may give some guidance.

- 1 Bacteriologically positive sputum indicates activity and is an absolute indication for treatment.
- 2 The presence of symptoms such as cough, haemoptysis, tiredness or loss of weight is suggestive that a lesion demonstrated radiologically is active.

- 3 The presence of crepitations on auscultation, especially if persistent, is in favour of activity.

- 4 Certain radiological appearances suggest activity: a cavity (unless there has been previous effective treatment); soft shadows, especially if widespread; and shadows that extend on serial chest films.

Unless the lesion has calcified there is a risk of reactivation of pulmonary tuberculosis, although the risk varies with age and the type of lesion [162–164]. The more extensive the lesion, the younger the patient and the softer the opacity, the more likely is relapse with active tuberculosis. The risk of reactivation is 10 or more times greater than the same risk in tuberculin-positive patients with a normal chest film and can be diminished by chemoprophylaxis [165–168]. Nevertheless, most clinicians in the UK would not treat or give prophylactic isoniazid to such patients, who have no symptoms suggesting activity, have stable chest films and are bacteriologically negative. They should be advised to present themselves for radiography should they develop new respiratory or systemic symptoms suggestive of activity. In the author's experience, annual chest films for such patients are uneconomic and largely unproductive, since patients who do reactivate usually present with symptoms between attendances, like those who relapse following chemotherapy [169].

### **Clinical features in the HIV-positive patient**

The clinical features of tuberculosis in the HIV-positive patient depend on whether tuberculosis is developing early or late in the course of HIV infection [100,170–178]. Tuberculosis tends to occur earlier in the course of HIV infection and in this situation the clinical, radiological and bacteriological findings do not differ substantially from those found in HIV-negative patients. The disease is predominantly pulmonary, located in the upper lobes and cavitation occurs. Tuberculin tests are usually positive and sputum smear positivity is not decreased.

When tuberculosis occurs later in the course of HIV infection or in patients with AIDS the features are more often atypical: pulmonary disease may occur in atypical sites, e.g. lower zone or diffuse consolidation, mediastinal adenopathy is more common and involvement of extrapulmonary sites such as brain, pericardium, bones and the gastrointestinal tract is found [179–181]. Cavitation of pulmonary lesions and tuberculin positivity are less common. Sputum smear negativity may be more common [182].

### **Differential diagnosis of pulmonary tuberculosis**

The most important conditions from which tuberculosis has to be distinguished are pneumonia, carcinoma of the bronchus, lung abscess and pulmonary infarct. In certain regions of America coccidioidomycosis, and histoplasmosis in both America and parts of Africa, have to be consid-

ered. In the developed world as tuberculosis declines, disease due to atypical mycobacterial infection may cause confusion.

### Pneumonia

A segmental pneumonia with soft upper zone opacities may mimic pulmonary tuberculosis. In contrast to tuberculosis, where symptoms may be absent or prolonged, the acute pneumonic patient usually has symptoms of fairly recent onset. A history of contact with tuberculosis may suggest this diagnosis in young people. The diagnosis of tuberculosis is made by sputum examination and tuberculin testing. If the patient is symptomatic, an oral antibiotic should be prescribed and if the radiographic opacities have not cleared or improved in 2–3 weeks then tuberculosis is more likely.

Acute bacterial pneumonia requiring hospital admission sometimes proves to be tuberculous and it is wise to bear this possibility in mind should response to antibiotics not occur. With pneumonia refractory to standard treatment, especially if the white cell count is normal, repeated sputum specimens should be examined for acid-fast bacilli.

### Carcinoma of the bronchus

This differential diagnosis arises in the middle-aged and elderly age groups. Consolidation distal to a proximal carcinoma, particularly in the upper zone, may be cavitated and closely mimic tuberculosis. Occasionally, primary tuberculosis in the elderly presents with a peripheral lesion and enlarged hilar nodes, closely mimicking carcinoma (see Fig. 17.2). Sputum examination for malignant cells and acid-fast bacilli may differentiate the two but bronchoscopy may be required to make the diagnosis. If no tumour is seen and the sputum is negative on direct smear, bronchoscopic specimens should be obtained for direct smear and culture for acid-fast bacilli. Both conditions may of course coexist.

With isolated solid pulmonary opacities, the presence of satellite lesions or calcification, perhaps only detectable on CT, suggests tuberculosis. If bacteriologically negative, it may be possible to establish a diagnosis by transbronchial biopsy or fine-needle aspiration but if this fails then thoracotomy is mandatory, assuming the patient is fit enough for this procedure. If there is any doubt about the lesion, a positive tuberculin test should not delay thoracotomy.

Isolated cavities may also give rise to difficulties. Irregularity of the wall or polypoid protrusions into the interior suggest carcinoma, while satellite lesions or calcification favour tuberculosis. Bilateral shadows suggest tuberculosis. If sputum examination and biopsy attempts are unrewarding, thoracotomy should be considered to establish the diagnosis.

### Lung abscess

Lung abscess due to *Staphylococcus pyogenes* or *Klebsiella pneumoniae* is usually an acute severe illness with marked leucocytosis and the organism readily isolated from blood or sputum. There may be multiple abscesses. With cavitary tuberculosis the sputum is usually, but not always, positive on direct smear.

### Pulmonary infarction

Upper zone pulmonary infarcts, especially if bilateral and/or cavitating, may give rise to diagnostic difficulty. Routine investigations, evidence of deep vein thrombosis and serial chest films that show rapid change in pulmonary infarction usually readily distinguish the two conditions.

### Other pulmonary diseases

Tuberculosis enters into the differential diagnosis of many other pulmonary diseases and sputum examination and tuberculin testing are essential in the investigation of abnormal pulmonary shadows. Atypical mycobacterial disease is a frequent source of diagnostic confusion (see Chapter 20).

## Complications

### Pleurisy

Pleurisy occurs commonly in pulmonary tuberculosis. A classical pleural rub may be heard (see Chapter 43).

### Tuberculous empyema

Tuberculous empyema was commonly found following artificial pneumothorax therapy. It still presents as many as 30 years after initial infection [183]. It is now rare but may be seen in association with pleural effusion complicating severe pulmonary disease or as the result of rupture of a cavity into the pleural space [184]. The diagnosis is made by the demonstration of acid-fast bacilli on direct smear in pus from the pleural space. Chemotherapy and tube suction may resolve the situation but further surgical procedures such as decortication may be indicated [184,185].

### Tuberculous laryngitis

This is seen in patients with positive sputum and relatively severe disease. It causes hoarseness progressing to pain on swallowing. Lesser lesions, such as oedematous arytenoids, may be detected on laryngoscopic examination [186]. Biopsy is important in establishing the diagnosis.

### Tuberculosis of other organs

Tuberculosis may not be confined to the lung. In the male the testes should be examined routinely, and routine examination of the urine for tubercle bacilli is advisable.

### Chronic obstructive airways disease

There is no doubt that a clinical pattern of disease almost indistinguishable from that of chronic bronchitis and emphysema with severe airways obstruction may result in patients with severe fibrotic pulmonary disease following tuberculosis [187–189].

### Cor pulmonale

A logical extension of chronic obstructive airways disease is that some patients develop cor pulmonale secondary to extensive fibrotic disease, with distortion of pulmonary parenchyma, emphysema and airways obstruction. Early treatment obviates this late complication of pulmonary tuberculosis.

### Amyloidosis

This complication is now rare but may still be seen in association with a tuberculous empyema. Diagnosis may be made by the staining of rectal, mucosal, liver or kidney biopsies.

### Aspergillomas

Infection of tuberculous cavities by *Aspergillus fumigatus* is well recognized (Fig. 17.10). Most give rise to no major problems apart from occasional haemoptysis from which sudden death rarely occurs. Surgical resection of lesions causing major problems (i.e. massive haemoptysis) may be feasible [190,191] provided pulmonary function is adequate (see Chapter 21).

### Carcinoma of the bronchus

There is no definite evidence that carcinoma of the bronchus is more common in patients with inactive tuberculous disease. However, both are common in cigarette smokers and may occur together. The concept of 'scar carcinoma', although attractive, has never been fully established [192].

### Adult respiratory distress syndrome

The adult respiratory distress syndrome may complicate postprimary tuberculosis [193].

### Pulmonary tuberculoma

Tuberculoma presents occasionally as an incidentally discovered solitary pulmonary nodule. If there is any doubt about the nature of the lesion, then it is best resected since

**Fig. 17.10** Aspergillomas in old tuberculous cavities: the upper cavity contains an aspergilloma and shows the classical air crescent sign; the lower cavity has a fluid level with an aspergilloma protruding above it.

the principal differential diagnosis is from bronchogenic carcinoma [194].

### Poncet's disease

Finally, and scarcely a complication but an accompani-

ment of postprimary pulmonary tuberculous disease, mention must be made of Poncet's tuberculous polyarthritides [195]. First described in 1897, and reiterated as recently as 1984 [196], this polyarthritides, resembling rheumatic fever, may occur in association with postprimary pulmonary tuberculosis. It resolves with treatment.

# EXTRA-PULMONARY TUBERCULOSIS

R. ANDREW SEATON

Tuberculosis is an increasing problem for the developed world, particularly among the economically deprived [1], the growing immigrant population and elderly, debilitated or frankly immunosuppressed patients. Human immunodeficiency virus (HIV) infection is a well-recognized risk factor for both activation of initial infection and reactivation of latent infection. In the USA, patients with AIDS are 54 times more likely to have tuberculosis than the rest of the population and patients with tuberculosis are 204 times more likely to have AIDS [2]. The incidence of extrapulmonary features tends to increase with advancing immunosuppression in HIV-infected persons. However, the burden of both HIV infection and tuberculosis is greatest in sub-Saharan Africa; in Zambia, 49% of patients with pulmonary tuberculosis are HIV-antibody positive and the incidence of HIV infection increases to 84% when extrapulmonary sites are involved [3]. Similar trends can be expected to develop in Asia, where tuberculosis is already endemic, as HIV seroprevalance grows [4]. In other developing countries, such as India and Papua New Guinea, a failure of local control programmes has meant that tuberculosis remains a major public health problem despite relatively low HIV seroprevalance rates. Despite this, tuberculosis is emerging as a significant cause of morbidity in the increasing HIV-infected population [5]. This chapter is primarily concerned with describing the clinical features of extrapulmonary disease, which worldwide comprises approximately 10–50% of all tuberculosis presentations in HIV-negative patients [6,7] and 35–80% in HIV-infected patients [2,7,8]. In Scotland in 1993, extrapulmonary tuberculosis accounted for approximately 21% of tuberculosis notifications in the Caucasian population and 53% of such notifications in the Indian subcontinent population [9]. The commonest manifestations of extrapulmonary tuberculosis are superficial lymphadenitis, genitourinary disease, pleural disease, miliary disease, bone and joint disease and abscesses of the soft tissues (Table 18.1). Pericardial disease is of particular importance in HIV-infected patients in the developing world and mycobacterial bacteraemia may be detected

in most HIV-infected patients with tuberculosis. Most forms of extrapulmonary tuberculosis are readily diagnosed and treated, provided a high index of suspicion is maintained. However, there is evidence through autopsy surveillance that extrapulmonary tuberculosis is underdiagnosed in both the developed and underdeveloped world. In the USA, 18% of miliary, meningeal and peritoneal tuberculosis is diagnosed after death [10]; in HIV-infected patients in Italy, only 70% of autopsy-proven extrapulmonary tuberculosis is diagnosed clinically [11]. In African patients with HIV-related 'slim disease' (patients previously thought to be wasted due to chronic enteric infections), autopsy studies have shown that disseminated tuberculosis is significantly correlated with wasting [12].

When diagnosed, the presence of extrapulmonary features may have important implications with respect to management, particularly in considering the use of adjuvant therapies such as corticosteroids and surgery, but all forms require standard antituberculous treatment as described in Chapter 19. Pulmonary tuberculosis and pleural disease are covered in Chapters 17 and 43. Where appropriate, special mention is made of therapy in organ-specific tuberculosis.

## Central nervous system tuberculosis

Central nervous system (CNS) tuberculosis is a particular problem in infants and children, in whom disease occurs as a complication of primary infection, but it also complicates miliary disease in both adults and children. In patients with tuberculosis and HIV infection there is a significantly greater risk of meningeal disease than in the non-HIV-infected tuberculosis population [13].

## Pathology

The most common manifestation of CNS tuberculosis is meningitis. The meninges are presumably infected at the time of disease dissemination and it is the breakdown of

**Table 18.1** Distribution of extrapulmonary tuberculosis in Lothian, Scotland in 1993. (Adapted from Leitch *et al.* [9].)

Site of tuberculosis	Percentage
Lymphatic	37.5
Genitourinary	23.4
Pleural	12.5
Miliary	8.6
Bone and joint	5.5
Cold abscess	4.7
Gastrointestinal	3.1
Meningitis	3.1
Pericardial	0.8
Skin	0.8

meningeal granulomas with seeding of the cerebrospinal fluid (CSF) and extension of the process that leads to the clinical manifestations. The basal meninges are usually covered with a gelatinous exudate that contains lymphocytes, fibrin and caseating granulomas. This inflammatory process may extend into the cerebrum or cerebellum, where larger collections, or tuberculomas, are formed. Alternatively, and possibly more commonly, tuberculomas may arise from blood-borne dissemination of infection and may present as mass lesions. The most frequent site for operatively proven intracerebral tuberculomas is the posterior fossa, where 67% of all mass lesions are found. Multiple lesions occur in about 16% of patients. Coexistent meningitis is relatively rare in the presence of intracerebral tuberculoma in non-HIV-infected patients [14]. Involvement of the basal meninges commonly leads to cranial neuropathies and the exudative process may also cause obstruction of CSF flow, leading to hydrocephalus. Arteritis may also develop and lead to cerebral and brainstem infarction [15]. Encephalitis with oedema and gliosis of brain tissue is also recognized and increased intracranial pressure may result in tentorial herniation of the brainstem. Cerebral tuberculous abscesses are histologically distinct from the more common cerebral tuberculomas and depend on the finding of macroscopic pus in the abscess cavity with acute inflammatory changes within the abscess wall associated with *Mycobacterium tuberculosis*. Abscesses are thought to arise because of haematogenous spread from a pulmonary focus; they tend to be solitary and progress more rapidly than tuberculomas [16].

### Clinical features

These are usually insidious and take the form of malaise, fever, weight loss, headache, diplopia, altered consciousness and meningism. Cranial neuropathies, particularly involving the abducens, oculomotor and facial nerves, are common and sensorineural deafness is also recognized. In infants, failure to thrive and bulging fontanelles may be

presenting features and late presentation may result in severe neck retraction. Focal neurological signs, such as hemiparesis, monoparesis, quadriparesis and cerebral paraplegia, may occur when tuberculomas are present [15] or indeed may arise as a result of arteritis and infarction. A variety of other neurological syndromes have also been described, including tremors (generalized or parkinsonian), hemiballismus, myoclonic jerks and cerebellar ataxia [15]. Symptoms and signs of raised intracranial pressure, such as coma, generalized convulsions, systolic hypertension and papilloedema, may also be present. Symptoms and signs in HIV-positive patients are similar, although other opportunistic infections commonly coexist [13] and other CNS diseases should also be excluded whenever possible [16,17].

### Differential diagnosis

As this depends on the mode of presentation, the site of the tuberculous lesions, the presence or absence of HIV infection and the origin of the patient, the differential diagnosis is wide. Tuberculous meningitis must be differentiated from bacterial and fungal meningitis, particularly cryptococcal meningitis which occurs in approximately 5% of AIDS patients in the UK [18] and in 10% of those in the USA [19], where it is one of commonest life-threatening opportunistic infections. In immunocompetent patients in some tropical settings, cryptococcal meningitis is commoner than tuberculous meningitis [20] but can be easily differentiated by positive serum or CSF cryptococcal antigen assays or by india ink staining and culture of CSF. Viral meningitis may be rarely confused with tuberculous meningitis owing to the relative lymphocytosis in CSF.

The differential diagnosis of a space-occupying lesion includes primary or secondary brain tumours and particularly medulloblastomas in the posterior fossae of children. Intracerebral cysticercosis must also be differentiated in endemic areas [21].

### Investigations

The majority of CNS tuberculosis is diagnosed in the developing world where resources are often poor. Therefore a high index of suspicion should be maintained in all neurological syndromes in endemic areas and often the response to empirical antituberculous therapy is the most valuable diagnostic tool.

The examination of CSF is mandatory in any suspected case of tuberculous meningitis and characteristically demonstrates pleocytosis (>20 cells and >60% lymphocytes) on direct microscopy, although early in the disease process polymorphonuclear cells may predominate. CSF protein concentration is usually raised (>500 mg/L) and CSF glucose is usually less than 60% of corresponding

blood sugar. In some, but particularly HIV-positive patients, CSF protein concentrations may be normal; less frequently CSF may be acellular [13,22]. CSF parameters may also vary depending on the level from which the specimen is retrieved. A patient with hydrocephalus seen recently demonstrated normal CSF in a ventricular sample but examination of a lumbar sample revealed a marked lymphocytosis. The diagnosis is established by demonstrating acid-fast bacilli following Ziehl–Nielsen staining or by fluorochrome staining of CSF, which is slightly more sensitive. However, microscopy may only be positive in one-quarter of patients. Culture of CSF on Lowenstein–Jensen medium or by guinea-pig inoculation has a higher diagnostic yield than direct CSF examination but takes 3–6 weeks and therefore seldom affects initial management. Newer methods such as radiometric technology using liquid media (Bactec, Becton Dickinson) provide more rapid results but still take between 2 and 3 weeks [2,7]. An enzyme-linked immunosorbent assay (ELISA) that detects CSF mycobacterial antigens has proved both sensitive and specific [23] as has detection of tuberculostearic acid in CSF [24], although these techniques are not widely available. The polymerase chain reaction has recently been used to validate traditional methods of diagnosis and has been found to be positive in 86% and 75% of patients with highly probable and probable tuberculous meningitis respectively. These results were found to correspond to the clinical response to chemotherapy [25].

The tuberculin test is difficult to interpret in CNS tuberculosis in adults, particularly in the immunosuppressed population, who may be anergic, and in endemic areas where the majority of adults can be expected to have had prior exposure to tuberculosis. However, in infants a positive tuberculin test may be helpful. Clinical features of extrameningeal tuberculosis are usual in both HIV-infected [13,17] and non-infected patients [26]. Hyponatraemia is frequently found [27] and may result from inappropriate antidiuretic hormone secretion [28], as in other organic brain syndromes, rather than as a result of adrenal insufficiency, which appears to be uncommon in tuberculosis [29].

Neuroradiological scanning has contributed greatly to the diagnosis and management of CNS tuberculosis, particularly in detecting hydrocephalus, which has been demonstrated in 87% of children and 12% of adults with tuberculous meningitis [30]. Tuberculomas appear on cerebral CT as isodense, hypodense or hyperdense rounded lesions, 1.5–7 cm in diameter with peripheral enhancement and perifocal oedema after the injection of contrast [31]. Lesions are calcified in 38% of patients with meningitis and in 1–6% of those with tuberculomas [32]. Magnetic resonance imaging (MRI) may also be useful [33] but probably does not add to information gained by CT. In India, ring- or disc-enhancing lesions on CT in

patients with epilepsy were found to be most commonly due to cysticercosis, although tuberculomas accounted for 14% of all biopsied lesions [21]. In HIV-infected patients with tuberculous meningitis, CT has been found to be abnormal in 69% and appearances are similar to those in non-HIV-infected patients [13].

### Treatment and prognosis

The treated mortality in CNS tuberculosis is 20–50% [34] including those infected with HIV [13]. In survivors the sequelae can be devastating; in India 53% of survivors had permanent sequelae, 41% of whom had moderate to severe disability, such as hemiparesis, involuntary movements, substantial mental impairment, inability to function independently or a persistent vegetative state [35]. With this background of treatment failure despite antituberculous chemotherapy, much attention has been focused on the use of adjuvant corticosteroids. It has been postulated that they could improve morbidity and mortality by reducing cerebral oedema, cerebral vasculitis and the formation of exudate, thereby preventing the development of hydrocephalus [34]. The development of cerebral tuberculomas during antituberculous chemotherapy, associated with neurological deterioration, has also been described in patients with meningitis as well as in those with extrameningeal disease [36,37], and corticosteroids are probably beneficial in this situation [36]. Some favour their use in all patients with tuberculous meningitis [38], although the risk of reduced CSF penetrance of antituberculous drugs (by restoring the blood–brain barrier) are an important consideration when treating patients with less severe disease [39]. A randomized controlled trial of 43 patients in India suggested that sequelae were reduced in dexamethasone-treated patients, although no significant statistical difference was noted and there was no difference in mortality [40]. An older but larger study had suggested that corticosteroids improved survival [41], although this has been criticized because of its high overall mortality (51%), the large number of patients lost to follow-up and its method of analysis [34]. Another study has suggested that steroids may improve mortality when used to reduce cerebral oedema in patients with severe disease but the numbers were small (23 patients) and the results not statistically different [42]. The British Medical Research Council has defined three stages of CNS tuberculosis [43]: stage I or mild cases, with no alteration in consciousness and without neurological signs; stage II or moderately advanced cases, with altered consciousness (but not comatose) and mild focal neurological deficits; and stage III or severe cases, who are comatose with multiple neurological deficits (including multiple cranial nerve palsies and bilateral neurological signs). Using these definitions a large Chinese study [44] has purported to show reduced mortality in stage II and III disease with no

difference in stage I disease. With no controlled studies yet showing increased mortality or morbidity with corticosteroid use in the later stages, the current consensus is to use these drugs in stage II and III disease at a dose equivalent to prednisolone 1 mg/kg daily for 30 days, followed by a gradual reduction in the dose over the next few weeks [34]. As yet, corticosteroid use in HIV-related CNS tuberculosis has not been evaluated.

There are few data to support the neurosurgical resection of all tuberculomas as they tend to respond to chemotherapy [32,33]. However, tuberculomas of the posterior fossa may require drainage, and the mechanical relief of hydrocephalus due to adhesions may also improve outcome [39]. In a series of 48 patients with tuberculous meningitis managed in a French intensive care unit, 15 patients underwent insertion of a CNS prosthetic device for the treatment of hydrocephalus. Despite this aggressive treatment 11 died, with neuroradiological signs of cerebral infarcts in nine, while one survivor had severe neurological sequelae. In two patients, death was attributed to nosocomial infection of the prosthetic device [45].

Prolonged adjunct therapy with interferon (IFN)- $\gamma$  and granulocyte colony-stimulating factor has been reported to cure an immunocompromised patient with refractory multidrug-resistant tuberculous meningitis [46]. In this case there was complete resolution of neurological and radiological signs following the introduction of this adjunct therapy. The proposed mechanism of action is via IFN- $\gamma$  activation of monocytes and macrophages against tuberculosis in the immunosuppressed patient.

### Superficial tuberculous lymphadenitis

This is the commonest form of extrapulmonary tuberculosis in both HIV-infected and non-infected patients [2,7]. Involvement of lymph nodes may result from direct extension of infection or from haematogenous spread. In developing countries, lymph node tuberculosis most commonly affects young adults [47,48]. In the UK, most cases are seen in patients of Indian subcontinent origin [49]. Non-Caucasian patients with lymphadenitis are usually aged 10–50 years, whereas Caucasians tend to be older than 50 [50–52].

#### Clinical features

The patient usually presents with slow painless swelling of cervical or submandibular nodes (Fig. 18.1). Other sites may also be involved, including supraclavicular, inguinal and axillary nodes (Fig. 18.2) and there may be multiple swellings. Occasionally the onset may be acute and painful with a perinodal reaction. Fever may occur but is more common in HIV-infected patients [53]. A cold abscess or sinus may form.

Fig. 18.1 Left-sided submandibular tuberculous lymphadenitis.

#### Investigations

The diagnosis is established by culture of material obtained via node biopsy, excision or fine-needle aspiration. Wide-needle aspiration of tuberculous lymph nodes under local anaesthesia has been successfully employed in Africa, with a sensitivity of 74.8% and specificity of 97.4% [54]. Pathological examination of tissue may show typical tuberculous histopathology. Mycobacterial lymphadenitis in children is most commonly due to non-tuberculous mycobacteria, whereas in adults *M. tuberculosis* is the usual infecting organism [48,55]. Patients with HIV infection have a poor cellular response and are less likely to demonstrate caseating granulomas [55]. Typically, in HIV-infected patients, smears of infected nodes demonstrate a greater burden of organisms than in HIV-negative patients, reflecting advanced immunosuppression [56]. Whereas HIV-infected patients usually have evidence of parenchymal lung disease, only 25–30% of HIV-negative patients have evidence of pulmonary involvement [53,57].

### Tuberculous pericarditis

Pericarditis is a serious and life-threatening manifestation of tuberculosis. Although it is rare in developed countries,

**Fig. 18.2** Left-sided axillary tuberculous lymphadenitis.

in some developing countries it is the commonest cause of pericardial disease and an important cause of heart failure [58]. Prior to the emergence of HIV infection, tuberculous pericarditis was seen most frequently in the Caucasian population in the third, fourth and fifth decades [59,60], and accounted for 11% of all pericarditis where a specific cause was documented [58]. In the UK, most cases occurred in patients of Asian origin of whom 88% were under the age of 45 [60]. In some developing countries pericardial disease is as common in children as it is in adults [58,61]. HIV infection is now known to be strongly associated with pericardial tuberculosis; 84% of African patients with tuberculous pericardial effusions are infected with HIV [3] and in the HIV-infected population tuberculosis is the commonest cause of a large pericardial effusion [62].

### Pathogenesis

The disease begins either by infiltration of the pericardium by a caseous node or by miliary spread. The heart becomes covered by a fibrinous, caseous material that with the exudate can result in pericardial effusion. If the process heals by fibrosis, then constrictive pericarditis ensues [58]. Tuberculous mediastinal lymphadenitis may lead to the formation of a fistula between a bronchus and the pericardium, resulting in pneumopericardium and occasionally cardiac tamponade [63].

### Clinical features

The commonest symptoms of pericardial disease are weight loss, cough, dyspnoea, orthopnoea, chest pain and ankle swelling. The most commonly elicited signs are fever, tachycardia, pericardial rub, paradoxical pulse,

hepatomegaly, oedema, neck vein distension, muffling of the heart sounds, abdominal distension, ascites and hepatomegaly. The clinical signs vary depending on the degree of effusion or constriction. Signs of constriction are most distinctive, with raised jugular venous pressure and a prominent 'Y' descent [58]. Friction rubs are usually absent but a diastolic knock with a third heart sound are typical. Inspiratory splitting of the second heart sound is usually found [58]. Symptoms and signs are similar in HIV-positive and HIV-negative patients, although HIV-positive patients are more frequently pyrexial and constriction is less frequently seen [63].

### Investigations

Chest radiography consistently shows cardiomegaly when pericardial effusions are present but the heart size may be normal when constriction predominates. Calcification of the pericardium is infrequently seen. Pleural effusions are seen in 40–77% of patients and other radiographic abnormalities, particularly pneumonia and mediastinal lymphadenopathy, are also common [58,62]. Electrocardiographic abnormalities occur in most, notably low-voltage complexes and T-wave inversion or flattening [58]. Echocardiography reveals pericardial effusion with or without pericardial thickening and fibrinous or caseous debris. Diastolic collapse of the right atrium is characteristically seen in patients with significant effusions and M-mode studies may demonstrate impaired left ventricular function [61]. Pericardial aspiration usually reveals blood-stained fluid, although it may be straw-coloured [58,61]. Microscopy may show a lymphocytic exudate but smears for acid-fast bacilli are negative in most cases [61]. *M. tuberculosis* can be isolated by culture in up to 50% of patients [59]. In HIV-positive patients in developing coun-

tries, a presumptive diagnosis of tuberculosis can be made on the basis of a pericardial effusion alone [62], although cardiomegaly and heart failure must be differentiated from primary HIV cardiomyopathy in patients with more advanced HIV disease. A high index of suspicion must be maintained in other patients, in whom the differential diagnosis includes pyogenic, malignant and autoimmune-related pericardial disease. In developing countries and in patients of African or Asian origin, amoebic pericardial effusions should be considered, particularly if symptoms are acute. Serodiagnosis, using a solid-phase antibody competition sandwich ELISA, has recently been evaluated and has a sensitivity of 61% and specificity of 96% [64]. This technique may prove useful in patients in whom it is not possible to culture pericardial fluid.

### Treatment

The response to chemotherapy is variable and most authorities advocate adjuvant corticosteroid treatment [38], with or without pericardiocentesis and/or pericardectomy. Complete open drainage of pericardial fluid on admission has been shown to reduce significantly the need for subsequent pericardiocentesis but does not appear to influence the need for pericardectomy for subsequent constriction or the risk of death [65]. Adjuvant prednisolone during the first 11 weeks of chemotherapy significantly reduces the risk of death due to pericarditis and also reduces the need for repeated pericardiocentesis [66]. The dose of prednisolone in adults is 60 mg daily for the first month, 30 mg daily for the second month, 15 mg daily for 2 weeks and 5 mg daily for the final week. In patients presenting with constriction, prednisolone significantly reduces pulse rate and jugular venous pressure [66]. However, both parameters are comparable to those of patients receiving chemotherapy alone following discontinuation of prednisolone after 11 weeks [66]. Long-term follow-up of patients with constriction treated with prednisolone shows a more rapid return to unrestricted activity and a reduction in mortality related to pericarditis. However, the need for subsequent pericardectomy is not reduced and is necessary in 21–30% of patients. Pericardectomy is indicated for those not responding to chemotherapy and corticosteroids, particularly in refractory heart failure where operative intervention may be life-saving.

### Bone and joint tuberculosis

Bone and joint tuberculosis is a common manifestation in developing countries, occurring in up to 20% of all patients with diagnosed active tuberculosis [67]. In the UK, bone and joint disease is less common, occurring in about 5% of all tuberculosis notifications [68], with about half of these cases occurring in patients of Asian origin.

Disease is most common in children and young adults in developing countries [69]. Tuberculosis of the skeleton usually arises as a result of haematogenous spread and is said to occur 1–5 years after primary infection [70].

### Clinical features

Half of all bone and joint infections involve the spine, with the weight-bearing joints involved next most commonly [7,67]. Other sites can be involved, including the elbow and shoulder [71,72], the wrist [73], hands and fingers [67], and the non-articular skeleton including the ribs, scapula and skull [74,75]. The risk of bone and joint tuberculosis may be increased in patients with underlying inflammatory joint disease, particularly those receiving corticosteroid therapy [71], and may postdate pulmonary tuberculosis by years [73,76].

Spinal tuberculosis or Pott's disease is commonest in the lower thoracic and lumbar regions [69,77] but may also affect the cervical spine [67,73,78]. The vertebral bodies and intervertebral discs are most commonly affected. The usual presentation is with local pain, stiffness and limitation of movement. Diagnosis is often delayed and symptoms may have been present for months or years before presentation. Often a recent fall or apparent back trauma precipitates admission to hospital, resulting in the fortuitous discovery of spinal tuberculosis. Between 14 and 23% of patients present with clinically detectable abscess or sinus formation [77,79] (Fig. 18.3) and rarely with isolated abdominal symptoms due to an associated psoas abscess [80]. Neurological signs are present in 6–12% of patients [67,69,77,79] and vary depending on the spinal level involved. At worst the patient may present with complete motor and sensory loss in the lower limbs with loss of sphincter control [81]. Cervical spine involvement may present with quadriplegia, while lumbosacral tuberculosis is usually not associated with a neurological deficit [82]. Neurological signs may sometimes develop or worsen during chemotherapy, but in the majority of patients these neurological deficits improve [81]. Neurological involvement is caused by direct pressure on the cord from sequestered bone and disc, granulation tissue and pus, or spinal cord instability [78]. Less frequently, tuberculous inflammation crosses the dura to involve the meninges and spinal cord. Late-onset paraplegia is also well described and may occur years after the development of spinal deformity [78,83]. This may arise as a result of vascular insufficiency, prolonged angulation of the cord over an internal gibbus or reactivation of the tuberculous process [78]. Gibbous deformity, kyphosis and other spinal deformities occur in patients with more advanced disease due to collapse of vertebrae.

Systemic symptoms are variably present in spinal tuberculosis, but about 40% of patients experience weight loss [84]. Radiological evidence of past or present pulmonary

**Fig. 18.3** Lumbar hump due to Pott's disease complicated by a cold abscess to the right.

tuberculosis is present in 42% [77,84], although other forms of extrapulmonary tuberculosis are rarely encountered [67].

Tuberculosis of other peripheral bones and joints presents with chronic progressive pain, stiffness and swelling (Fig. 18.4), and a history of previous trauma is often elicited [72]. Systemic symptoms are present in about half of patients and soft tissue abscesses and sinuses may also be associated. Pulmonary tuberculosis is detected in approximately half of these patients [72].

### Radiological features

In early spinal disease, diminution of the disc space with erosion of end-plates is seen, with subsequent destruction and collapse of vertebral bodies (Figs 18.5 & 18.6). In about 60% of patients at least three or more vertebrae are

**Fig. 18.4** Tuberculosis of the second metacarpal with cold abscess formation in an Asian patient.

involved [69,79] and in 5% lesions extend from the thoracic spine to the sacrum [69]. Of patients with spinal disease, 57% have plain-film evidence of psoas or paraspinal abscess [77], although when CT is employed abscesses are detected in 91% [84]. In Bombay the clinical diagnosis of spinal tuberculosis was confirmed when MRI was used in 23 of 24 symptomatic patients with normal spinal radiographs [85].

In peripheral joint tuberculosis the commonest radiographic abnormalities are bony erosions and destructive changes, joint space narrowing, asymmetry of condyles (knee joints), osteopenia, cortical cysts and pathological fractures [72].

### Diagnosis

For the most part diagnosis is based on clinical and radiological evidence, particularly in spinal disease where histological or microbiological diagnosis may not be feasible. A high index of suspicion should be maintained in all age groups in developing countries. In developed countries the immigrant population and patients with previously documented or suspected tuberculosis are also at greater risk. Spinal disease should be differentiated from metastatic disease, particularly in developed countries where

**Fig. 18.5** Pott's disease of the spine affecting the T12/L1 disc space and adjacent vertebrae.

Pott's disease is rare. Rapid diagnosis of early lesions may be made if MRI is available. Peripheral joint disease may be more difficult to diagnose and depends on the exclusion of other infective and non-infective arthritides, including gout, rheumatoid arthritis, connective tissue disease and sarcoidosis. Culture of synovial fluid may be positive in 64% and typical caseating granulomas are seen in about half the patients who undergo synovial tissue biopsy [71,72]. Stains for acid-fast bacilli in synovial fluid are infrequently positive [71,72].

### Treatment

The majority of patients with spinal tuberculosis respond to short-course chemotherapy alone, including those with sinuses or abscesses on admission [69]. Results are less favourable on regimens that do not include rifampicin. Immobilization of the spine with a plaster-of-Paris cast is no longer advocated [79]. In specialist units with vast experience, the 'Hong Kong' operation, which involves resection of lesions and anterior spinal fusion with autologous bone grafts, has proved successful but is not a substitute for chemotherapy [77]. In a large series of paraplegic patients treated with chemotherapy alone, 72% were func-

**Fig. 18.6** (a) Early tuberculous changes in the lumbar spine showing disc narrowing at L1/2, destruction of the body of L2 and demineralization of the adjacent end-plate. (b) The same patient 17 months later showing mild gibbous deformity resulting from extensive collapse of L2.

(a)

(b)

tionally and neurologically normal between 1 and 6 years of follow-up and 84% were sufficiently recovered to walk unaided. Only 6% of patients were left paralysed and unable to walk [81]. The role of surgery is yet to be clearly defined but is probably applicable to only a small percentage of patients with severe, deforming disease and then only in specialized centres. As the majority of spinal disease occurs in the developing world where such surgical expertise may be lacking, it is encouraging to see the success of new short-course chemotherapy regimens. In peripheral joint tuberculosis chemotherapy is also the mainstay of treatment [71].

### Gastrointestinal tract and peritoneal tuberculosis

Abdominal tuberculosis occurs infrequently in the indigenous population of the UK but is an important disease in migrants from Asia, in whom the incidence is highest in those under the age of 50 [86]. In the USA, two distinct groups are recognized as being at increased risk of abdominal tuberculosis: migrants from developing countries and patients infected with HIV [87]. In developing countries, peritoneal tuberculosis is a relatively common cause of ascites, and other forms of abdominal tuberculosis occur frequently enough to merit inclusion in any differential diagnosis of abdominal pain, organomegaly or abdominal mass, particularly in young adults with constitutional symptoms.

#### Pathogenesis

The peritoneum and viscera (liver, spleen and pancreas) may be involved via the bloodstream, usually following reactivation of foci from a primary lung focus, although

haematogenous spread may complicate active pulmonary tuberculosis or miliary tuberculosis (Fig. 18.7). Contiguous spread from mesenteric lymph nodes, intestine or fallopian tubes may also occur. The majority of patients with peritoneal tuberculosis have ascites at the time of presentation but a small proportion may have a 'dry' fibroadhesive form of the disease [88]. The gastrointestinal tract may be involved via four mechanisms: (i) swallowing infected sputum; (ii) ingestion of contaminated milk (rare in developed countries); (iii) haematogenous spread; and (iv), rarely, direct extension from adjacent organs. The ileocaecal area and jejunum are the commonest sites of tuberculous involvement but any level, from the oesophagus to the anus, may be involved. Pathologically most inflammation takes place in the submucosa and serosa, leading to bowel wall thickening and later fibrosis. Ulceration occurs in some as a result of endarteritis of submucosal vessels [88]. Intestinal narrowing may occur as a result of stricture formation or by extrinsic compression from enlarged mesenteric lymph nodes.

#### Clinical features

One-quarter to half of all patients with abdominal tuberculosis present with peritoneal tuberculosis [86,88–90]. Symptoms develop insidiously over weeks or months, with abdominal swelling due to ascites; most have fever, weight loss, abdominal pain and tenderness. In patients with ascites, particular attention must be paid to their cardiovascular status as pericardial disease may present similarly. About 16% of patients with peritoneal disease also present with diarrhoea [89]. Evidence of active pulmonary tuberculosis is present in up to half and 48–62% have abnormal chest radiographs suggestive of active or healed pulmonary tuberculosis [88,89]. Peritoneal tuberculosis

**Fig. 18.7** Biopsy of peritoneal lesion showing tuberculous granuloma.

also accounts for about one-fifth to half of all cases of abdominal tuberculosis in patients with HIV infection [87,91], although absence of pain and abdominal findings are not uncommon.

Tuberculosis of the small bowel and colon also presents insidiously with non-specific symptoms. Abdominal pain is present in most, diarrhoea in one-fifth, weight loss in two-thirds and fever in 35–50% [88]. Nausea, vomiting, melaena and rectal bleeding may also be presenting features. Abdominal tenderness is elicited in most patients, and up to 50% have a palpable mass in the right iliac fossa [88]. A 'doughy abdomen' due to extensive intra-abdominal inflammation may also be detected.

The commonest complication of small bowel disease is obstruction, which occurs in about 20% of patients [88]. This may arise because of inflammatory thickening of the bowel, stricture formation, adhesions, or extrinsic obstruction due to mesenteric lymphadenitis. Perforation and fistula formation, massive bleeding and malabsorption may also occur.

Disease of the large bowel may mimic inflammatory bowel disease, with segmental ulcers, colitis, strictures and polyps. Patients present with palpable masses, bleeding, obstruction, perforation and sinus formation. Isolated anorectal disease mimicking Crohn's disease may be present.

Oesophageal disease is less common than small and large bowel disease. It usually arises as a result of direct extension from mediastinal lymph nodes or from a pulmonary focus [88,92]. Less commonly, oesophageal tuberculosis may arise in the absence of tuberculosis elsewhere. Patients typically present with dysphagia, odonophagia, aspiration due to tracheo-oesophageal fistulae and minor haematemesis. Although an uncommon manifestation of tuberculosis in the non-HIV-infected population, this manifestation may be more common in HIV-infected patients [93].

Gastric tuberculosis is also rare and the clinical presentation is likely to be confused with peptic ulcer disease. Duodenal disease is most commonly confused with neoplasm, peptic ulcer and Crohn's disease. In the HIV-infected population, the duodenum is the commonest gastrointestinal site for *M. avium-intracellulare* infection [94].

Patients with tuberculosis may present with hepatomegaly in conjunction with gastrointestinal tract or peritoneal disease [87,95,96] or in isolation as a hepatic abscess. Splenomegaly has been found to be present in one-third of patients with abdominal tuberculosis in Egypt [90]. Splenic involvement in patients with HIV infection is also described, usually in association with constitutional symptoms, with or without evidence of pulmonary disease [97,98]. Tuberculosis of the pancreas is rare but may present with all the features of acute pancreatitis [99].

Abscesses, particularly of the psoas muscle and mesenteric lymph nodes, occur frequently in abdominal tuberculosis and may lead to abdominal masses with or without sinus formation and occasionally to intestinal obstruction. Formation of abscesses, particularly in abdominal tuberculosis, appears to be a common complication in AIDS-related tuberculosis [100].

## Diagnosis

The diagnosis of abdominal tuberculosis is easily missed and is frequently made only following exploratory laparotomy in developed countries [89]. A high index of suspicion is required in developing countries where resources may be poor and treatment empirical. The diagnosis should be considered particularly in migrants to developed countries and in the HIV-infected population.

Plain film radiography may reveal a psoas abscess or evidence of past or present pulmonary tuberculosis. Ultrasound scans may show thickened, conglomerated loops of bowel, mesenteric lymph node enlargement or hypoechoic regions in the liver and spleen [97]. CT may be similarly useful.

Peritoneal tuberculosis may be diagnosed by paracentesis of ascites, although acid-fast bacilli are usually absent or scanty. Culture of peritoneal fluid increases the yield to 66–83% but is time-consuming and for the best results requires the centrifugation of 1 L of fluid [88]. Peritoneal biopsy is best performed laparoscopically or by mini-laparotomy. Characteristically, small (<5 mm) white 'miliary' deposits are seen and adhesions between the peritoneum and organs are common. Blind peritoneal biopsy is also frequently used, particularly in developing countries, but has a lower yield than more invasive procedures. Ascitic fluid protein greater than 25 g/L, a serum-ascites albumin gradient of less than 11 g/L and ascitic lactate dehydrogenase greater than 90 iu/L are sensitive in differentiating tuberculous peritonitis from ascites due to chronic liver disease [101]. The concentration of adenosine deaminase in peritoneal fluid is the most useful non-invasive method of diagnosis, levels greater than 33 u/L having a sensitivity and specificity of 100% and 95% respectively [88]. Its usefulness in HIV infection has yet to be determined. Ascitic IFN- $\gamma$  has been shown to have a sensitivity and specificity of 100% at a cut-off of 3 and 9 u/mL and in one study was shown to reduce false positives detected by raised adenosine deaminase [102]. The cost of this test makes it infeasible for use in developing countries.

Diagnosis of tuberculosis of the gastrointestinal tract requires a high index of suspicion. The clinical, radiological and endoscopic picture is most commonly confused with Crohn's disease, although the differential diagnosis includes yersiniosis, amoebiasis, neoplasm and gastrointestinal histoplasmosis. Gross endoscopic findings are

non-specific but biopsies (most usefully from ulcer margins) identify caseating granulomas or acid-fast bacilli in 35–60% of cases [88]. Again, culture of crushed tissue increases the yield but is time-consuming. Exploratory laparotomy may be required in difficult cases. Splenic aspiration and liver biopsy under ultrasound control have proved useful in HIV-infected patients [97]. Otherwise a therapeutic trial of antituberculous chemotherapy is justified in the presence of suggestive clinical findings.

### Management

Most patients respond well to chemotherapy, including 6- and 9-month regimens. Surgery is indicated for massive bleeding, obstruction, free perforation and confined perforation with abscess or sinus formation. Although widely used, there is no evidence that corticosteroids have a role in any form of abdominal tuberculosis.

### Genitourinary tract tuberculosis

Genitourinary tract tuberculosis is a common form of extrapulmonary tuberculosis, accounting for 18–22% of cases in the USA [95,96] and up to 41% of cases in Spain [103]. In Scotland about 20 new cases are seen annually per 1 million population [104] and in Europe it is estimated that 1% of renal replacement therapy results from tuberculosis [105]. Unlike other forms of extrapulmonary tuberculosis in the UK, genitourinary tuberculosis appears to occur relatively more frequently in Caucasians than in the Asian population [106]. However, this difference seems to be related to the older age of Asian patients with genitourinary tract tuberculosis and also to the higher incidence of other forms of extrapulmonary tuberculosis in the Asian population. Thus in the UK the occurrence is very similar in the two ethnic groups [107]. In developing countries, genital tract tuberculosis occurs most frequently in women of child-bearing age [108], whereas in developed countries the disease occurs most frequently in postmenopausal women [109]. Localized genitourinary tract tuberculosis is rarely diagnosed in HIV infection, although urine cultures are frequently positive in patients with disseminated tuberculosis [2].

### Pathogenesis

Genitourinary tract tuberculosis results from haematogenous spread to the kidney, with subsequent spread to the ureters, bladder, prostate, seminal vesicles, epididymis and female genital tract. It usually arises secondary to a previous primary focus and the time interval from primary infection has been estimated to be between 1 and 46 years [104]. About one-quarter of patients with urinary tract tuberculosis have a history of previous tuberculosis

and about 38–80% of women with genital tract tuberculosis have evidence of extragenital tuberculosis [103,110]. Prior to chemotherapy, the majority of patients dying from pulmonary tuberculosis had bilateral renal involvement [111]. However, nowadays unilateral involvement is more common. Rarely, isolated tuberculous interstitial nephritis may occur in the absence of other renal tract abnormalities [105].

### Clinical features

Commonly, patients present with frequency, dysuria, loin pain, nocturia and haematuria. Scrotal swelling due to epididymo-orchitis may occur and may be complicated by sinus or abscess formation [112]. Less commonly, clot colic or haematospermia may be the presenting symptoms. Constitutional symptoms such as weight loss and asthenia occur in up to 60% of patients [104]. Interstitial nephritis presents with progressive renal impairment and other symptoms and signs may be absent [105]. Female genital tract tuberculosis presents with infertility, menorrhagia, amenorrhoea or pelvic inflammatory disease, and in about 50% of cases adnexal masses are palpable on pelvic examination [109,110].

### Diagnosis

A history of recurrent urinary tract infection or pyuria with negative bacterial cultures should lead to the suspicion of renal tract tuberculosis, particularly if unexplained fever, perineal sinuses, a beaded vas deferens, scrotal sinus or induration of the prostate or seminal vesicles are noted on examination. Early morning urine specimens should be sent for microscopy and culture for acid-fast bacilli. About 48% will have positive Ziehl–Nielsen stains and the remainder will be culture positive after about 3 weeks [103]. An intravenous pyelogram is abnormal in most cases and may show calcification, dilatation of the calyces or loss of definition of minor calyces, hydronephrosis, hydroureter or a non-functioning kidney. Renal cavitation, multiple ureteric strictures or a shortened refluxing ureter may also be seen [95,96]. Radiological evidence of involvement of both the upper and lower renal tract is highly suggestive of tuberculosis [103]. Tuberculous interstitial nephritis can only be confidently diagnosed following renal biopsy, which demonstrates diffuse interstitial nephritis and caseating granulomas. In these patients, microscopy and culture of urine is frequently negative for mycobacteria [105]. Female genital tract tuberculosis is usually diagnosed following the histological or microbiological examination of endometrial curetting [109]. Histological examination of the fallopian tubes in such patients invariably shows tuberculous involvement and in 20–40% of cases the ovaries are also involved [110].

## Management

The surgical management of genitourinary tuberculosis is largely reserved for severe or life-threatening complications such as haemorrhage, severe hypertension or suspicion of malignancy [103]. Nephrectomy for a single non-functioning kidney is no longer recommended. Corticosteroids have been advocated to relieve symptoms of cystitis or in speeding the resolution of ureteric obstruction [38] and also appear to be obligatory in the treatment of tuberculous interstitial nephritis [105].

## Cutaneous tuberculosis

Cutaneous tuberculosis [113–115] is very uncommon but may present in one of six ways.

**1** A primary complex, usually on the face or a mucous membrane, may arise due to direct inoculation of *M. tuberculosis*. A well-demarcated, ulcerating papule (tuberculous chancre) is present, which is often painless, and the local lymph nodes are infected (Fig. 18.8).

**2** Miliary tuberculosis (tuberculosis cutis miliaris acuta generalisata) classically occurs in immunocompromised children and results in symmetrical crops of papules, vesicles and necrotic lesions. It occurs only rarely in the immunocompetent adult [116], but recently has been noticed in increasing frequency in patients with advanced HIV infection [117,118]. Miliary disease in the HIV-infected patient may also present with a localized painful fluctuant swelling [118].

**3** Verrucous tuberculosis is an occupational hazard of pathologists and others working with infected material and usually presents as a painless papule or papulopustule that evolves into a warty hyperkeratotic plaque,

often on the back of the hand. The lesion may resolve spontaneously after several years.

**4** Orificial tuberculosis, consisting of painful ulcers around the mouth, nose or anus, may be the presenting sign of pulmonary or gastrointestinal tract tuberculosis.

**5** Colliquative tuberculosis or scrofuloderma results from direct infection and breakdown of skin overlying a tuberculous focus, such as a lymph node, bone, joint or epididymis.

**6** Lupus vulgaris begins with brownish-red discoloration. It gradually expands to form a soft brownish-red serpiginous plaque with apple-jelly nodules. It may occur anywhere on the body but is most common on the face. It is chronic, resulting in scarring and occasionally the formation of deep erosive ulcers.

The diagnosis of tuberculosis of the skin is made by a pathological and bacteriological examination of a representative biopsy. Smear-positive lesions occurring in the absence of other clinical manifestations of tuberculosis must be differentiated from infection with other mycobacterial species, particularly the *M. avium-intracellulare* complex in patients with advanced HIV infection [118].

## Tuberculosis of the breast

Tuberculosis of the breast (Fig. 18.9) is a rare manifestation of tuberculosis. It is a disease of younger women in developing countries and is usually unilateral. In the UK it occurs most commonly in women of Asian origin [119]. The breast probably becomes involved by retrograde lymphatic extension from primary foci of the disease in the lymph nodes of the mediastinum, axilla, parasternal and cervical regions. It could also result from haematogenous invasion or by spread of infection from adjacent tissues.

**Fig. 18.8** Tuberculous ulcer at base of anterior triangle of neck, with associated regional lymphadenopathy (circled).

**Fig. 18.9** Gross enlargement of the breast due to tuberculosis.

Patients invariably have previous or coexistent evidence of tuberculosis elsewhere [119] but the diagnosis must be confirmed by the demonstration of acid-fast bacilli in needle aspirates. Histological findings typical of tuberculosis must be differentiated from a granulomatous reaction to a breast cancer as well as other infectious granulomatous reactions [120].

### Ocular manifestations of tuberculosis

Ocular manifestations of tuberculosis are rare, occurring in only 1.4% of patients [114,121]. Phlyctenular conjunctivitis is characterized by a single vesicular lesion near the limbus surrounded by an area of erythema. It rapidly becomes a small yellowish ulcer and heals within a few weeks. Direct bacillary involvement of the conjunctiva has been recognized. Tuberculous keratitis and scleritis usually result from the spread of infection and granulomatous reaction from within the eye. The orbit is most frequently involved following contiguous spread from orbital periostitis.

Granulomatous lesions have been described from all parts of the uveal tract but the posterior choroid is the commonest site. Retinal oedema is seen in the earliest stages but, untreated, choroidal nodules usually appear. Larger lesions heal with choroidal and retinal scarring and this process may be complicated by retinal detachment and neovascularization. Panuveitis always accompanies choroidal disease. Choroidal tubercles may be seen in about half of patients with miliary tuberculosis. Tuberculous meningitis may also result in optochiasmal chorioiditis.

Specific antituberculous treatment leads to rapid resolution of the eye lesions. Local treatment with corticosteroids and mydriatics can also be given and severe disease may be managed with adjuvant corticosteroids.

teroids and mydriatics can also be given and severe disease may be managed with adjuvant corticosteroids.

### Tuberculosis of the upper respiratory tract

Tuberculosis of the upper respiratory tract (Fig. 18.10) occurs in about 1.8% of tuberculosis admissions [122] and is normally accompanied by pulmonary disease. The larynx is most commonly involved and this form of tuberculosis is highly infectious. As well as the systemic features of tuberculosis, hoarseness, cough and odynophagia are prominent symptoms. The laryngoscopic appearance varies from beefy-red erythema to oedema and frank ulceration. Tuberculosis of the larynx must be differentiated from laryngeal carcinoma by smears or biopsy of the involved tissue [123]. Lateral soft tissue radiography of the neck, tomography of the larynx and contrast laryngography are the radiological techniques commonly used to assess laryngeal involvement [123].

Tuberculosis of the nasal mucous membranes is extremely rare and can mimic Wegener's granulomatosis [124]. Diagnosis is confirmed by biopsy or smears.

Tuberculous otitis media usually presents with deafness, facial palsy, multiple perforations and painless otorrhoea [125]. Otagia may also occur [122,126] and the presentation may be complicated by secondary infection. Smear and/or culture of material is diagnostic in about half of patients and the diagnosis relies on histological examination in the remainder [125]. The results of antituberculous therapy are good, although tympanoplastic surgery may be required in those in whom there is extensive destruction of the tympanic membrane.

Fig. 18.10 Tuberculosis of pharynx and soft palate.

### Tuberculous bacteraemia

Tuberculous bacteraemia [127] is detected in 20–50% of patients with HIV-associated tuberculosis [2] but is rare in HIV-negative patients with tuberculosis [128]. In AIDS, 83% of patients with disseminated tuberculosis [128] and 71% with pulmonary involvement [129] have positive blood cultures. In some HIV-positive patients with advanced immunodeficiency, blood may be the only site from which *M. tuberculosis* is isolated. In developed countries where tuberculosis is not endemic, a positive mycobacterial blood culture in the HIV-infected individual is considerably more likely to be due to infection with

the *Mycobacterium avium* complex [130]. Thus initial therapy, pending speciation, should be targeted against this complex unless there is also clinical evidence of tuberculous infection.

### Acknowledgement

This chapter has been modelled on the original text by the late Gordon Leitch in the fourth edition of this book. His contribution to the contemporary study of tuberculosis in Scotland and his influence on the writing of this chapter is greatly appreciated.

# MANAGEMENT OF TUBERCULOSIS

A. GORDON LEITCH

The history of tuberculosis treatment has been fully documented by Keers [1]. Prior to the 1950s the mainstay of management was bedrest, fresh air, sunshine (where available) (Fig. 19.1) and, in suitable cases, surgical intervention. Resection of tuberculous lesions was performed, but much more commonly the active management of tuberculous lesions depended on 'collapse therapy'. Collapse therapy 'rested' diseased lung and might take the form of artificial pneumothorax (Fig. 19.2), induction and maintenance of a pneumoperitoneum (Fig. 19.3), phrenic nerve crush or the performance of a thoracoplasty. Thoracoplasty involved the resection of five, seven or, exceptionally, 11 ribs on the affected side to cause collapse of the underlying lung [2] (Fig. 19.4). An additional surgical development was collapse of the lung induced by pleural plombage, in which the pleura, and hence the underlying lung, were compressed by implanted material, most commonly lucite balls and less commonly mineral oil [3].

The discovery of streptomycin and of its activity against mycobacteria by Schatz and Waksman in 1944 [4] heralded a new era of tuberculosis chemotherapeutics. The antimycobacterial effect of para-aminosalicylic acid (PAS) was first described by Lehmann [5] and this was followed by isoniazid in 1952 [6]. The British Medical Research Council were quick to investigate streptomycin treatment of tuberculosis in one of the world's first controlled trials [7]; 21% of the controls died and only 8% showed radiographic improvement, whereas in the treated group 51% showed radiographic improvement and only 7% died. In this study, many patients who had initially improved with streptomycin treatment deteriorated after 3 months and it became apparent that in most cases treated with streptomycin alone, mycobacterial resistance to this drug emerged after 3 months of treatment. With the development of PAS and isoniazid, subsequent Medical Research Council studies confirmed that monotherapy led to the emergence of drug-resistant bacteria (e.g. to isoniazid alone [8]), whereas combinations of drugs (streptomycin and PAS, streptomycin and isoniazid, PAS and isoniazid)

were shown to be more effective and to prevent the emergence of drug-resistant organisms [8–10]. These early observations were further developed in Edinburgh, where it became apparent and was subsequently reported in 1958 that if tuberculous disease was caused by fully drug-sensitive organisms it was possible, employing suitable combination therapy with streptomycin, PAS and isoniazid, to prevent the emergence of drug-resistant organisms and to effect a 100% cure [11,12].

With these early regimens it was necessary to continue therapy for 18 months or 2 years. With the passage of time and the introduction of new drugs the emphasis has been placed on devising courses of chemotherapy that are as effective and which sterilize tuberculous lesions in the shortest possible period [13–17]. The rationale of such short-course chemotherapy is outlined below.

## Rationale of short-course chemotherapy

### Bacterial populations in tuberculous lesions

Following ingestion by macrophages, tubercle bacilli are released with the development of caseation (Fig. 19.5). The low oxygen tensions prevailing in caseous tissue do not favour rapid multiplication of bacilli. Following liquefaction of caseous tissue and cavity formation, the prevailing oxygen tension is much higher, favouring extracellular bacillary multiplication. Continuing ingestion of bacilli by macrophages with further caseation and cavity formation extends the process. It has been estimated that the population of slowly growing organisms in macrophages and caseous lesions/tissue is less than  $10^5$ , whereas in cavities the rapidly growing population numbers  $10^7$ – $10^9$  organisms [14]. Since mutants resistant to streptomycin, isoniazid and ethambutol in wild strains of tubercle bacilli number 1 per  $10^5$ – $10^6$  organisms and those resistant to rifampicin 1 per  $10^7$  [14], such strains could easily be selected by therapy with one drug. Such selection is

**Fig. 19.1** Open air treatment of pulmonary tuberculosis by rest and fresh air in the grounds of the Royal Victoria Hospital, Edinburgh, c. 1920.

**Fig. 19.2** Chest radiograph showing an induced artificial pneumothorax for treatment of disease in the left lung. Adhesions have prevented complete collapse.

avoided by multiple drug therapy. The aims of therapy are the speedy elimination of the large population of rapidly dividing organisms in cavities (bactericidal action) and the sterilization of the slowly dividing organisms (the persisters) in cells and caseous tissue. The available antituberculosis drugs make different contributions to these bactericidal and sterilizing actions.

**Fig. 19.3** Chest radiograph showing artificial pneumoperitoneum.

### Activity of the principal antituberculosis drugs

From studies of the fall in sputum bacterial counts in the early days of treatment with single drugs, it has been established that isoniazid is the most potent bactericidal agent, rifampicin is less bactericidal and streptomycin and pyrazinamide have only low bactericidal activity [18]. The sterilizing activity of drugs has been particularly studied in the experimentally infected mouse, where rifampicin and pyrazinamide are very potent sterilizing drugs [19]. Isoniazid plus either rifampicin or pyrazinamide are the

**Fig. 19.4** Chest radiograph showing a five-rib thoracoplasty on the left side with underlying treated pulmonary tuberculosis (50 years on).

**Fig. 19.5** Bacterial populations in the lesions of human tuberculosis. (From Grosset [14].)

most potent combinations and the addition of streptomycin or ethambutol to these combinations adds little to their sterilizing capacity.

It is thought that different populations of bacteria exist within tuberculous lesions and each is particularly accessible to the action of a different antituberculosis drug [13]. One population of rapidly growing bacilli, e.g. in cavity

walls, is particularly vulnerable to the action of isoniazid. Two separate slowly growing populations are selectively affected by pyrazinamide and rifampicin. Pyrazinamide is believed to be particularly effective against bacilli in an acid (presumably intracellular) environment, since it is only an efficient antibacterial agent *in vitro* at a pH of 5.6 or less. Rifampicin has been shown to be a particularly effective bactericidal agent for dormant bacilli which have short bursts of metabolic activity [20]. Finally, a fourth population of totally dormant bacilli not killed by any drug is believed to exist.

The principles of current short-course chemotherapy are outlined in Fig. 19.6. Rapidly multiplying extracellular bacilli are killed by isoniazid and, to a lesser extent, rifampicin and streptomycin. Slowly growing bacilli in cells and caseous lesions, the persisters, are sterilized by the action of isoniazid, rifampicin and pyrazinamide. Failure to achieve adequate sterilization leads to relapse and it has now been established that the shortest course of chemotherapy required for adequate sterilization with currently available drugs is 6 months [21]. Suitable regimens are reviewed later in this chapter.

## Antituberculosis drugs

Modern drug treatment regimens consist of an initial or introductory phase of therapy followed by a maintenance or continuation phase of therapy.

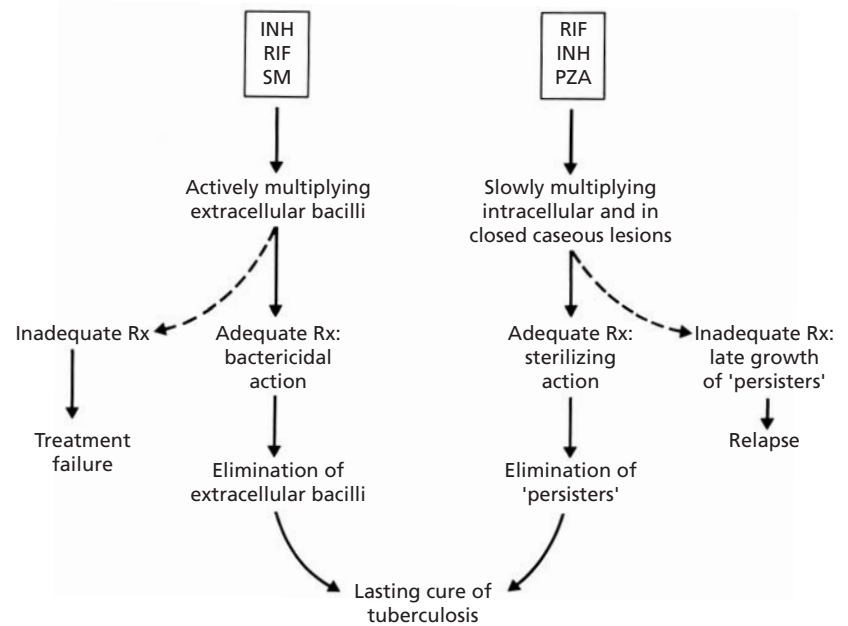

### First-line drugs

First-line drugs are those used in initial and maintenance chemotherapy unless drug resistance is known. The standard dosages for daily and intermittent therapy in children and adults and the commoner side-effects of these drugs are shown in Table 19.1.

### Rifampicin

Rifampicin is a semisynthetic broad-spectrum bactericidal antibiotic derived from *Streptomyces mediterranei*. It was the introduction of this antibiotic that permitted the development of the first effective short course of 9-month chemotherapy for tuberculosis [22,23]. In addition to its antituberculosis activity, it has a wide range of activity against other bacteria, including *Staphylococcus*, *Streptococcus*, *Clostridium*, coliforms, *Pseudomonas*, *Proteus*, *Salmonella*, *Shigella*, *Bacterioides* and *Legionella*.

Rifampicin is almost completely absorbed from the gastrointestinal tract after an oral dose and is partly deacetylated in the liver by an enzyme induced in the first few days of treatment. When taken on an empty stomach, peak plasma levels of 6–7  $\mu\text{g/mL}$  are reached at 3 h and the drug has a half-life of about 5 h [24]. Most strains of *Mycobacterium tuberculosis* are inhibited *in vitro* by concen-

**Fig. 19.6** Principles of modern chemotherapy of tuberculosis. INH, isoniazid; RIF, rifampicin; PZA, pyrazinamide; SM, streptomycin. (From Stead & Dutt (*Am Rev Respir Dis* 1982; 125: 94).)

**Table 19.1** Dosage and adverse effects of first-line antituberculosis drugs.

Drug	Dosage			Common adverse effects*
	Adult	Child	Intermittent	
Isoniazid	300 mg standard 5 mg/kg in chemotherapy 12 mg/kg in miliary	10 mg/kg	15 mg/kg	Hypersensitivity, hepatitis
Rifampicin	>50 kg, 450 mg >50 kg, 600 mg	10–20 mg/kg	600–900 mg 600–900 mg	Gastrointestinal, hypersensitivity, hepatitis Induction of liver enzymes Toxicity of intermittent therapy
Ethambutol	25 mg/kg for 2 months; then 15 mg/kg		Thrice weekly, 30 mg/kg Twice weekly, 45 mg/kg	Retrobulbar neuritis
Pyrazinamide	<50 kg, 1.5 g 50–74 kg, 2.0 g >75 kg, 2.5 g	40 mg/kg (max. 2 g)	Thrice weekly, 2.0 g Twice weekly, 3.0 g Thrice weekly, 2.5 g Twice weekly, 3.5 g	Arthralgia, hepatitis
Streptomycin	>30 kg, 750 mg >30 kg, 1 g (750 g if >40 years)	20 mg/kg (max. 1 g)	1 g	Ototoxicity (vestibular disturbance)

\*See text for detailed discussion of side-effects.

trations of 0.5 µg/mL. Although about 75% of the drug is protein bound, it penetrates well into tissues and cells. Therapeutic concentrations are reached in cerebrospinal fluid (CSF) when the meninges are inflamed. It is excreted almost entirely in the bile but there is enterohepatic circulation and some does appear in urine [25].

Rifampicin may be detected in urine following extraction of 10 mL urine by analytical-grade chloroform in a screw-capped tube by gentle tilting [26]. The test is negative if no colour develops, a yellow to orange colour in the

chloroform layer indicating the presence of rifampicin. The test is valid up to at least 6 h and, in some patients, up to 12 h after ingestion of rifampicin. Tetracyclines, nitrofurantoin and phenothiazine derivatives also give a yellow colour.

Rifampicin is available as capsules or tablets of 150 and 300 mg and as a syrup (100 mg/5 mL). Combined preparations with isoniazid and with isoniazid plus pyrazinamide are also available. An intravenous preparation may also be useful in certain clinical situations; 300 mg of red

lyophilized powdered rifampicin is reconstituted in 5 mL of solvent solution, diluted in 250 mL of infusion solution and infused over 2–3 h.

### Adverse effects

Serious adverse reactions to rifampicin are not common. The drug is excreted in body fluids and, as a consequence, all patients should be warned that their urine and also sweat and tears may be coloured orange-pink.

Of the gastrointestinal reactions, nausea, anorexia and mild abdominal pain are most common, with vomiting and diarrhoea occurring less frequently. These occur in less than 5% of patients and are more common in the elderly. They may be resolved by giving the drug at night or, if this fails, during a meal. Transient elevation in aspartate aminotransferase levels are common (14–40% of patients) and of no clinical significance. Major elevations of aspartate aminotransferase to greater than 150 iu/L occur in 4% and hepatitis with jaundice in about 1%. Risk groups for jaundice include elderly women, alcoholics and those with a previous history of liver or biliary disease [27]. Rifampicin should be administered with care to these groups. Concern about the rare development of acute hepatic necrosis in patients treated with rifampicin has led to the publication of management guidelines [28].

Cutaneous reactions are usually mild, consisting of flushing with or without itching or a rash, and commonly occur 2–3 h after taking the drug. Patients usually desensitize themselves to these reactions but occasionally an antihistamine may be required. Severe conjunctivitis and chronic papular acneform reactions of the head, neck and shoulders have also been described.

Cases of osteomalacia, pseudomembranous colitis, pseudoadrenal crisis, light-chain proteinuria with renal failure and cutaneous vasculitis have also been described [29–31].

Several other syndromes may occur with intermittent rifampicin regimens. The flu syndrome with flu-like symptoms lasting for up to 8 h after administration of the drug may occur a few months after treatment has been started and is attributed to the development of circulating rifampicin-dependent antibodies [32]. It may resolve spontaneously or necessitate a switch to a daily regimen. Thrombocytopenic purpura can occur and is an absolute indication for stopping therapy with rifampicin permanently. Asthmatic and hypotensive syndromes may occur separately or together and require corticosteroid therapy before conversion to a daily regimen. Acute haemolytic anaemia and acute tubular necrosis have also been reported. The incidence of side-effects in recent reports of intermittent therapy has been gratifyingly low [33,34].

Finally, rifampicin is a potent inducer of liver enzymes, resulting in increased metabolism of concurrently admin-

istered drugs. The contraceptive pill is unreliable during rifampicin therapy and alternative modes of contraception should be employed. Doses of corticosteroids [35], oral anticoagulants, oral diabetic agents, antiarrhythmic agents such as verapamil [36], theophyllines, digitalis, anticonvulsants, ketoconazole and cyclosporin [37] may need to be increased during therapy with rifampicin and be decreased thereafter.

### Isoniazid

Isoniazid is the most widely used antituberculosis agent. It is ideal in many respects, being bactericidal, relatively non-toxic, easily administered and inexpensive. It is readily absorbed from the gastrointestinal tract, with peak concentrations of approximately 5 µg/mL occurring about 2 h after administration [14]. Most strains of *M. tuberculosis* are inhibited *in vitro* by concentrations of 0.05–0.2 µg/mL. It penetrates well into all tissues including CSF. Some of the drug is excreted unchanged in urine but a proportion is acetylated by hepatic acetyltransferase to an inactive form.

An individual's rate of acetylation is genetically determined. Europeans and southern Indians are predominantly slow acetylators, with a mean serum half-life for isoniazid of about 3 h; the Japanese, Korean and Eskimo populations have a majority of rapid acetylators, with an isoniazid half-life of about 1.4 h. Differences in acetylator status do not influence the therapeutic efficacy of isoniazid nor are they related to the risk of isoniazid-induced hepatitis [38–41].

The drug is usually given orally and is supplied in 50 and 100 mg tablets or as an elixir containing 50 mg/5 mL. Combined preparations with rifampicin and rifampicin plus pyrazinamide are available. Isoniazid solution may also be given intravenously. Research into the development of a sustained-release isoniazid preparation, which would be of value in the treatment of poorly compliant patients, is ongoing [42,43].

### Adverse effects

Hepatitis is uncommon in the young but may approach a frequency of 2% when used chemoprophylactically in adults over 35 years of age [44]. Alcohol consumption is a definite risk factor. Peripheral neuropathy is the principal adverse effect and is more common in the malnourished, the elderly, patients with chronic liver disease, slow acetylators and in pregnancy [45]. It may be prevented by the simultaneous administration of 10 mg pyridoxine [46]. Larger doses (100–200 mg) of pyridoxine are needed to treat established neuropathy. Optic neuritis, psychosis and convulsions are less common side-effects [47]. Impaired concentration and excessive sleepiness may occur. Rarer adverse effects include pellagra in nicoti-

namide-deficient patients, haemolytic anaemia in glucose 6-phosphate dehydrogenase deficiency, agranulocytosis, lupoid reactions and arthralgia [38]. The interaction of isoniazid and phenytoin increases the serum concentration of both drugs; serum phenytoin levels should be monitored and the dosage decreased if necessary [16].

### Pyrazinamide

Pyrazinamide is bactericidal in an acid environment and has a sterilizing effect on intracellular mycobacteria [48,49]. *M. bovis* is resistant to the drug. It is well absorbed from the gastrointestinal tract, with peak concentrations of about 50 µg/mL occurring 1.5–2 h after ingestion. At a pH of 5.5 the minimal inhibitory concentration of pyrazinamide for *M. tuberculosis* is 20 µg/mL. It penetrates well into tissues including CSF.

The drug is available in 500mg tablets administered orally or in a combined preparation with rifampicin plus isoniazid. If intravenous therapy is required, lyophilized morphazinamide is available in 1-g vials for administration by drip infusion following reconstitution with solvent.

### Adverse effects

Hepatitis was commoner when higher doses of the drug were used than are now recommended (see Table 19.1). It occurs in about 1% of patients but milder subclinical derangement of liver function tests is common. The drug should be administered with caution to those with a history of liver or biliary tract disease. It should be noted that there is no significant increase in hepatotoxicity when pyrazinamide in standard dosage is added to a regimen of isoniazid and rifampicin during the initial 2 months of therapy [49]. Arthralgia is an uncommon adverse effect that appears in the first 2 months of treatment, more frequently in Chinese patients. It is due to inhibition of renal tubular secretion of uric acid by pyrazinoic acid, the main metabolite of pyrazinamide, and can be treated with non-steroidal anti-inflammatory agents [50]. High serum concentration of uric acid may uncommonly precipitate gout. Rarer adverse effects include anorexia, nausea and vomiting and sideroblastic anaemia [29].

### Streptomycin

Streptomycin is bactericidal in an alkaline environment. It is given parenterally by intramuscular injection and peak plasma levels in the range of 40 µg/mL are achieved 1 h after injection. Most strains of *M. tuberculosis* are inhibited *in vitro* at a concentration of 8 µg/mL. It diffuses readily into most body tissues, including CSF when meningitis is present. It crosses the placenta and fetal serum levels are about half those in maternal blood. The drug is excreted

almost entirely by glomerular filtration and dosage must be modified in renal failure to avoid toxicity.

Streptomycin sulphate for intramuscular injection is supplied as a powder in vials and should be reconstituted immediately before use. Between the ages of 40 and 60 years the dose should be reduced to 0.75 g; above 60 years it is wise to monitor serum levels, ensuring that trough plasma levels do not exceed 2 µg/mL [51].

### Adverse effects

Streptomycin is toxic to the eighth cranial nerve, with vestibular damage more common than auditory damage. The patient usually complains of progressive giddiness and unsteadiness of gait. Nystagmus may be present. The damage to the nerve is permanent but most patients eventually compensate via ocular and proprioceptive compensatory mechanisms. The risk increases with the dose of drug and with age [52,53]. Deafness occurs rarely. Streptomycin is ototoxic to the fetus. Other adverse effects include anaphylaxis, renal tubular damage and blood dyscrasias, including haemolytic and aplastic anaemia, agranulocytosis and thrombocytopenia [29]. Streptomycin potentiates the neuromuscular block produced by curare and is contraindicated in individuals suffering from myasthenia gravis.

### Ethambutol

Ethambutol is generally considered to be a bacteriostatic drug, although it is bactericidal *in vitro* [54]. It is well absorbed after ingestion, with peak plasma levels of 4 µg/mL occurring 2–4 h after a dose of 15 mg/kg [16]. Most strains of *M. tuberculosis* are inhibited *in vitro* by concentrations of the drug in the range 1–5 µg/mL. CSF concentrations of ethambutol are low (1–2 µg/mL with a dose of 25 mg/kg) even in the presence of meningitis. The drug is excreted in the urine and accumulates in patients with renal insufficiency. It is available in a combined preparation with isoniazid.

### Adverse effects

The principal adverse effect is retrobulbar neuritis [55–57], presenting with blurred vision, central scotomas and disturbance of red–green vision. Recovery is the rule if the drug is stopped at the first sign of visual problems but if these are ignored optic atrophy may result. This complication is uncommon at a dose of 15 mg/kg but increases with a daily dose of 25 mg/kg [56,58,59]. Patients should be warned to report visual symptoms immediately and to stop treatment if symptoms develop; pretreatment testing and recording of visual acuity is advised for patients taking this drug [57]. Particular care in dosage adjustment is necessary for those with renal impairment and the drug

**Table 19.2** Dosage and adverse effects of second-line antituberculosis drugs.

Drug	Dosage		Common adverse effects*
	Adult	Child	
Thiacetazone	150 mg	4 mg/kg	Gastrointestinal
Para-aminosalicylic acid (sodium salt)	10–20 g (in divided doses, twice daily)	300 mg/kg	Gastrointestinal, febrile cutaneous reactions
Ethionamide, prothionamide	<50 kg, 750 mg ≥50 kg, 1 g		Gastrointestinal, metallic taste in mouth
Cycloserine	500–100 mg (15–20 mg/kg)		Confusion, slurred speech, convulsions
Kanamycin, capreomycin, viomycin	As streptomycin (see Table 19.1); monitor serum urea and electrolyte concentrations		

\*See text for detailed discussion of side-effects.

is best avoided in young children. Serum levels should not exceed 5 µg/mL.

### Reserve drugs

Reserve drugs are used in the treatment or retreatment of patients with known or suspected mycobacterial drug resistance, usually to more than one drug as described later in this chapter. The usual dosage regimens and side-effects are shown in Table 19.2.

#### Para-aminosalicylic acid

PAS is a bacteriostatic drug, infrequently used in developed countries since the introduction of short-course chemotherapy regimens. It is bulky and unpleasant to take, the cachets being large in size and the tablets numerous. Twice-daily dosage may be needed. Combined preparations with isoniazid are available and should be used to avoid monotherapy. The drug may be detected in urine by Phenistix reagent strips, which turn reddish-brown in the presence of PAS.

#### Adverse effects

Gastrointestinal disturbance in the form of anorexia, nausea, vomiting and abdominal discomfort are common. Diarrhoea may be severe and result in a malabsorption syndrome [60]. Pulmonary eosinophilia may occur and be misinterpreted as deteriorating tuberculous disease. Haemolytic anaemia, thrombocytopenia and a glandular fever-like syndrome have been described. Prolonged administration of PAS may in rare cases produce hypothyroidism and goitre [61]. Hypersensitivity reactions may occur in 5–10% of patients.

#### Thiacetazone

Thiacetazone is a low-potency cheap drug given orally and is frequently used as a companion drug for isoniazid

in developing countries. It is poorly tolerated by Caucasians and the Chinese but better tolerated by Africans [62–65]. Natural resistance to thiacetazone occurs in varying proportions of mycobacterial strains [66] and there may be cross-resistance between thiacetazone and ethionamide. The drug is contraindicated in liver disease and in patients positive for human immunodeficiency virus (HIV).

#### Adverse effects

Generalized reactions (see later) are common. Nausea, abdominal discomfort and vomiting commonly occur. Other adverse effects include anaemia, agranulocytosis, thrombocytopenia, cerebral oedema, conjunctivitis, blurred vision and jaundice. Thiacetazone may enhance the ototoxicity of streptomycin.

Cutaneous hypersensitivity reactions progressing to toxic epidermal necrolysis have been reported in a significant percentage of patients with HIV-associated tuberculosis treated with thiacetazone-containing regimens in East Africa [67–69]. HIV-positive patients or those with clinical markers for AIDS should have ethambutol substituted for thiacetazone in their treatment regimen [69].

#### Cycloserine

Cycloserine given orally has weak bacteriostatic antimycobacterial action but may be valuable in preventing the development of resistance to companion drugs.

#### Adverse effects

The principal adverse effects are on the central nervous system [70]. Dizziness, slurred speech, headache, tremor, insomnia, confusion, depression and suicidal behaviour may result. Peripheral neuropathy may also occur and pyridoxine therapy should be given.

### Prothionamide and ethionamide

These two powerful drugs are similar in action, although prothionamide is considered to be the less unpleasant of the two [71–73]. It is taken in tablet form. Night-time dosage with an antiemetic taken 30 min before may be useful in maintaining treatment [16]. Thiacetazone-resistant organisms are often sensitive to prothionamide but the reverse does not apply.

#### Adverse effects

Anorexia, nausea or metallic taste in the mouth, salivation, vomiting and sulphurous eructations may occur. These may be alleviated by administration of prochlorperazine. Psychic disturbances, hypoglycaemia, hepatitis, gynaecomastia, menstrual disturbance and peripheral neuropathy may also occur. The drug should be avoided in pregnancy for it is teratogenic in animals, and care should be taken in the presence of diabetes, liver disease, alcoholism or mental illness.

### Capreomycin

Capreomycin is an aminoglycoside antibiotic administered by intramuscular injection. There is no cross-resistance between streptomycin and capreomycin.

#### Adverse effects

Capreomycin, like streptomycin, is ototoxic and causes high-frequency hearing loss *before* vestibular dysfunction occurs. Baseline and monthly audiometry as well as regular vestibular function assessment are recommended. The drug is also more nephrotoxic than streptomycin and care should be exercised in its use in the elderly and in those with renal impairment [74]. Hypokalaemia, hypocalcaemia and hypomagnesaemia have been reported [75]. Its use is contraindicated in pregnancy.

### Viomycin and kanamycin

These aminoglycosides are weak antituberculosis drugs, with essentially the same dose and adverse effects as capreomycin, although kanamycin is more likely to cause deafness than the vertigo seen with streptomycin. Audiometric assessment is therefore recommended.

### Recent additions to the list of effective drugs

#### Amikacin

Amikacin is an aminoglycoside that is highly bactericidal against *M. tuberculosis in vitro*. It is given as a single dose of 15 mg/kg by intramuscular injection five times weekly

**Table 19.3** Suggested dosages and adverse effects of newer antituberculosis drugs.

Drug	Adult dosage	Common adverse effects
Amikacin	15 mg/kg i.m. five times weekly	Nephrotoxic, eighth cranial nerve
Quinolones		
Ciprofloxacin	750–1500 mg once daily	Gastrointestinal symptoms
Ofloxacin	400–800 mg once daily	Gastrointestinal symptoms
Rifabutin	>50 kg, 150 mg >50 kg, 300 mg	Hepatotoxic Hepatotoxic

but can be given intravenously by slow injection over 30 min (Table 19.3).

#### Adverse effects

Amikacin is nephrotoxic and should be used with caution in patients with impaired renal function. The dose should be adjusted if necessary to ensure that peak serum levels 30 min after intravenous or 60 min after intramuscular administration remain in the range 35–45 µg/mL. Other side-effects include vestibular dysfunction and hearing loss, particularly in those aged over 60 years. Baseline audiometry is recommended.

### Quinolones

A number of fluoroquinolones show *in vitro* activity against *M. tuberculosis*. Both ciprofloxacin and ofloxacin have been used in treatment combinations for patients with multidrug-resistant tuberculosis and they appear to be effective. Ciprofloxacin in a single oral 750-mg dose produces a serum level of 2 mg/L, which compares favourably with the minimal inhibitory concentration against *M. tuberculosis* of 0.5–1 mg/L. Ciprofloxacin may have both bactericidal and sterilizing activities [76]. The doses recommended in Table 19.3 are sensible but the results of further clinical studies are needed before the full contribution of this class of drugs can be fully documented.

#### Adverse effects

The quinolones are remarkably free from serious side-effects. Gastrointestinal upsets, dizziness and hypersensitivity are the most common effects reported.

#### Rifabutin

Rifabutin is a member of the rifampicin family [77], with activity against *M. tuberculosis* and a side-effect profile resembling that of rifampicin [78]. In one *in vitro* study

rifabutin has been shown to have activity against 20% of rifampicin-resistant strains of tuberculosis [79] and it may therefore be of value in the management of drug-resistant disease provided that the results of sensitivity testing to both rifampicin and rifabutin are available prior to the initiation of treatment. The doses recommended in Table 19.3 are those employed in a study of HIV-associated tuberculosis in Uganda, where rifabutin compared favourably with rifampicin in combination chemotherapy and resulted in earlier sputum smear and culture conversion [80].

### Adverse effects

The side-effect profile resembles that of rifampicin, although it is a weaker inducer of microsomal enzymes [81].

### New drugs

There is an urgent need for new antituberculosis drugs [82]. Only a limited number of drugs are available and the readiness with which multidrug-resistant organisms may emerge even in the developed world is only too apparent (see below). Many developing countries already harbour a substantial minority of untreatable patients who survive to excrete and infect others with drug-resistant organisms. It would be foolish to presume that drug-resistant tuberculosis is destined to become less of a problem; at the very worst, in the not too distant future parts of the world may effectively return to the era before chemotherapy when, because of multidrug-resistant disease, there will be no effective therapeutic combination available for treatment.

Developing new antituberculosis drugs is an expensive exercise and tuberculosis is not a disease of rich nations: profits for the pharmaceutical industry are not in sight. Some development projects are underway [82] but more are needed. In the mean time, the report that clofazimine, an antileprotic agent, and some of its analogues have been shown to have activity against *M. tuberculosis* is to be welcomed [83]—tuberculosis doctors need all the help they can get.

## Generalized reactions to antituberculosis drugs

### Clinical manifestations

The principal adverse effects of individual drugs have been outlined above [22]. Any antituberculosis agent may produce a generalized hypersensitivity reaction, although this is less common with current short-course regimens than it was in the days of treatment with streptomycin, PAS and isoniazid. Occasionally, patients become sensitive to more than one drug. Such reactions are rare in the

first week of treatment and commonest in the second to fourth week, although they may also rarely occur late in therapy [84].

The usual manifestations are of fever and rash, the fever often preceding the rash by a few days. The rash is erythematous, macular or papular and usually itchy. It is most prominent on the face, neck and extremities. In severe cases, exfoliative dermatitis, Stevens–Johnson syndrome and anaphylaxis may occur, resulting rarely in death. In severe reactions, periorbital swelling, generalized lymphadenopathy, hepatosplenomegaly, encephalitis, rigors and high fever may occur. Acute myocarditis and pulmonary eosinophilia have been described.

## Management

### General management

Minor rashes, such as commonly seen with rifampicin, may be successfully treated with an antihistamine without having to stop chemotherapy. In the majority of cases treatment should be stopped until the rash has subsided to prevent progression of the reaction. If continued treatment for tuberculosis is deemed mandatory, then two drugs not previously employed to treat the patient should be introduced. Antihistamines and calamine lotion may be all that is required for subsequent amelioration of symptoms. Severe illness with hypotension or exfoliative dermatitis warrants systemic corticosteroid therapy, with intravenous hydrocortisone and prednisolone 40–60 mg orally per 24 h initially. The corticosteroid dosage can be titrated down subsequently according to the response.

### Identification of the offending drug(s)

When the reaction has subsided the patient should be challenged without delay with single drugs, beginning with those least likely to have caused the reaction. Once two drugs have been identified to which the patient is not hypersensitive, treatment may be restarted with these drugs while desensitization to the offending drug is carried out. It is vitally important that monotherapy should not be used since bacterial drug resistance has been known to develop during such carelessly conducted desensitization procedures. The sequence and doses of challenge regimens to be used to identify the responsible agent are shown in Table 19.4 [85], with the most likely offenders appearing at the foot of the table.

### Desensitization

If a hypersensitive reaction occurs to the challenge dose, then one-tenth of this dose should be used initially, doubling it every 12 h until full dosage is reached. Should a reaction occur during desensitization, the procedure

**Table 19.4** Challenge doses for detecting cutaneous or generalized hypersensitivity to antituberculosis drugs.

Drug	Challenge dose	
	Day 1	Day 2
Isoniazid	50 mg	300 mg
Rifampicin	75 mg	300 mg
Pyrazinamide	250 mg	1.0 g
Ethionamide, prothionamide	125 mg	375 mg
Cycloserine	125 mg	250 mg
Ethambutol	100 mg	500 mg
Para-aminosalicylic acid	1.0 g	5.0 g
Thiacetazone	25 mg	50 mg
Streptomycin or other aminoglycosides	125 mg	500 mg

If the reaction was severe, it is advisable to give smaller initial challenge doses, about one-tenth the doses shown for Day 1. If no reaction occurs to the challenge doses, then the drug may be resumed in full dosage *provided that another drug to which the patient is not hypersensitive is also prescribed in full dosage.*

should be resumed with a lower dose and conducted more slowly. In patients with severe reactions (except those who have had exfoliative dermatitis) and also if rapid desensitization is required, this may be done under cover of therapy with prednisolone 20 mg daily (40 mg in rifampicin-treated patients). The day after starting corticosteroid therapy one-quarter of the total dose is given in two divided doses, followed by one-half, three-quarters and full dosage on successive days. The dose of prednisolone can be gradually reduced thereafter, the rate depending on the severity of the initial reaction. Desensitization is infrequently required; the editors, with 100 years of chest medicine experience between them, have employed this procedure fewer than 10 times.

### Chemotherapy regimens for pulmonary tuberculosis

Most chemotherapeutic regimens that have been accepted as effective have been tested in patients with sputum smear-positive pulmonary tuberculosis. It is reasonable to presume that such regimens are also effective in smear-negative/culture-positive or culture-negative disease. In the developed world the same regimen is usually employed irrespective of the bacteriological status of disease. However, simpler (and cheaper) regimens have been developed in some countries for the treatment of smear-negative disease. These regimens and others are described after the account of standard short-course chemotherapy for compliant patients that follows. The relevance of compliance and the strategies that can be employed to guard against the emergence of drug-resistant organisms are dealt with fully in later sections; they assume major importance with the announcement of

**Table 19.5** Combined formulations of antituberculosis drugs that should be used in standard short-course chemotherapy.

#### *Initial phase of treatment*

Rifater tablets (containing rifampicin 120 mg, isoniazid 50 mg and pyrazinamide 300 mg)  
 <40 kg, 3 tablets  
 40–49 kg, 4 tablets  
 50–64 kg, 5 tablets  
 65 + kg, 6 tablets

#### *Continuation phase of treatment*

Rifinah or Rimactazid

<50 kg: Rifinah 150 or Rimactazid 150, 3 capsules (each containing rifampicin 150 mg and isoniazid 100 mg)  
 >50 kg: Rifinah 300 or Rimactazid 300, 2 capsules (each containing rifampicin 300 mg and isoniazid 150 mg)

Note: All medications to be taken fasting 30 min before breakfast.

the World Health Organization's worldwide commitment to the provision of DOTS (directly observed therapy, short course) in developing as well as developed countries.

### Compliant patients

#### Standard 6-month short-course chemotherapy

In Singapore, 6-month short-course chemotherapy, with an initial phase of 2 months of streptomycin, isoniazid, rifampicin and pyrazinamide followed by a 4-month continuation phase of rifampicin and isoniazid, was almost 100% successful in the treatment of pulmonary tuberculosis. If relapse occurred it was with fully sensitive organisms [86]. The British Thoracic Society have since confirmed these findings and demonstrated that streptomycin can be replaced by ethambutol 25 mg/kg in the initial 2-month phase without significant difference in therapeutic outcome [87,88]. With this regimen, 77% of patients had sputum conversion to culture negative at 2 months compared with only 64% on the standard 9-month regimen [88]. Wherever possible drugs should be given in combination formulations of proven bioavailability as an added protection against the emergence of drug resistance due to non-compliance (Table 19.5). The dosage regimen is illustrated in Table 19.6.

All drugs should be taken fasting 30 min before breakfast since concomitant food significantly decreases the bioavailability of rifampicin and isoniazid [89]. Because of the risk of ocular toxicity with ethambutol 25 mg/kg, the author has tended to use 15 mg/kg, which is safer and probably still perfectly adequate in fulfilling its role of preventing the emergence of resistant organisms in the few patients who may prove resistant to two of the other drugs. In any case, ethambutol can probably be omitted in patients with a low risk of isoniazid resistance [90,91].

**Table 19.6** Standard short-course chemotherapy: the 6-month regimen. (From British Thoracic Society [87,88].)

Isoniazid	300 mg orally	}	for 6 months
Rifampicin	600 mg (>50 kg) orally 450 mg (<50 kg) orally		
Pyrazinamide	1.5 g (<50 kg) orally 2.0 g (50–74 kg) orally 2.5 g (>75 kg) orally	}	for 2 months
Ethambutol	15–25 mg/kg orally, or		
Streptomycin	0.75 g i.m. 6 days out of 7		

Note: All orally administered drugs to be taken fasting 30 min before breakfast.

When the standard regimen is used it is important to remember to assess baseline visual acuity and baseline liver function and urate and to warn the patient of side-effects, particularly ethambutol on eyes and rifampicin on body fluids and other drugs (e.g. oral contraceptives).

### Assessing treatment response

In patients with positive bacteriology, sputum status should be assessed monthly; by 2 months more than 85% of positive sputum cultures should have converted to negative. Failure to convert should ring alarm bells about patient compliance and/or the emergence of drug-resistant disease. Drug sensitivity patterns should be rechecked and the need for supervised or directly observed therapy reviewed. It is helpful, if sputum is available, to document a negative sputum culture at the conclusion of therapy. Patients with fully sensitive organisms who have completed treatment need no regular follow-up but should be advised to report promptly should symptoms recur.

Clinically, after 1–4 weeks the patient should be feeling better, have gained weight and be free from fever, cough and sputum. Chest radiographic changes should have improved and may continue to improve over several months, eventually leaving residual fibrotic and/or cavitary change. Failure of the clinical or radiographic appearances to change after 2–3 months should lead to concerns about compliance and/or drug-resistant disease. If there is no bacteriological proof, the diagnosis should be reviewed.

### Infectivity following treatment

Most patients treated for tuberculosis are ambulatory or outpatient cases. Hospital admission is only necessary for severe disease, treatment or compliance problems. Patients are generally considered non-infectious after 2 weeks of chemotherapy and may return to work thereafter [92–94]. The decreased infectivity after 2 weeks is partly

due to the dramatic reduction in bacillary numbers in sputum and partly due to the reduction in cough. Clearly, however, live pathogenic bacteria are still present in sputum at this stage [95]. As a consequence, if the patient has been highly infectious, has persistent cough or is in regular contact with children or susceptible individuals such as hospital patients, the author prefers to keep the patient off work for at least 4 weeks.

### Monitoring for adverse reactions during standard short-course chemotherapy

Provided that baseline measurements of visual acuity and routine estimations of full blood count (including platelets), uric acid and liver function (bilirubin and hepatic enzymes) have been performed and patients know to report any new symptoms, routine monitoring of blood tests is not usually required. The patient should be seen at monthly intervals throughout therapy to allow clinical evaluation, including weighing and radiographic evaluation, at least initially. Further investigation is determined by clinical indications. A chest radiograph should be taken on completion of therapy.

### Other non-standard 6-month regimens

A number of studies from Singapore, Algeria, East Africa and Poland have described regimens based on an initial 1- or 2-month four-drug phase of therapy followed by a variety of 4-month intermittent or daily regimens that have had satisfactory success rates [86,96–100]. Since these regimens may be attractive for reasons of cost or the ability to supervise intermittent regimens in developing countries, they are listed in Table 19.7. However, it has been established by an American study that 6 months of rifampicin and isoniazid alone represents inadequate chemotherapy [101].

### Treatment of smear-negative pulmonary disease

In the developed world, standard short-course chemotherapy is employed. Two studies from North America have reported successful treatment of smear-negative disease with 6 months of dual therapy with rifampicin and isoniazid [102,103]. The success of different regimens in different geographical locations depends to a large extent on local disease factors (such as drug-resistance patterns) as well as social and cultural factors. National tuberculosis programmes in the developing world recommend the most appropriate regimens for smear-positive and smear-negative cases in their own countries where the luxury of routine mycobacterial culture and sensitivity pattern determination is usually not available [104,105].

**Table 19.7** Relapse rates with different 6-month chemotherapy regimens in patients with drug-sensitive bacilli.

Reference	Initial phase	Continuation phase	No. of subjects	Follow-up (months)	Relapse (%)
Singapore Tuberculosis Service/British Medical Research Council [86]	2SHRZ	4HRZ	84	6	0
	2SHRZ	4HR	80	6	1
Singapore Tuberculosis Service/British Medical Research Council [96]	2SHRZ	4H <sub>3</sub> R <sub>3</sub>	97	24	1
	1SHRZ	5H <sub>3</sub> R <sub>3</sub>	94	24	1
	2HRZ	4H <sub>3</sub> R <sub>3</sub>	109	24	1
Algerian Working Group/British Medical Research Council Co-operative Study [97]	2EHRZ	4HR	229	24	4
Third East African/British Medical Research Council Study [98]	2SHRZ	4TH	89	6	9
Tanzania/British Medical Research Council Study [99]	2SHRZ	4TH	105	24	3
Snider <i>et al.</i> [100]	2SHRZ	4H <sub>2</sub> R <sub>2</sub>	56	24	2
	2HRZ	4H <sub>2</sub> R <sub>2</sub>	116	24	3

E, ethambutol; H, isoniazid; R, rifampicin; S, streptomycin; T, thiacetazone; Z, pyrazinamide.

Subscripts indicate degree of intermittency, e.g. H<sub>2</sub> represents isoniazid twice weekly; numbers preceding letters indicate duration in months, e.g. 4HR represent 4 months of therapy with daily isoniazid and rifampicin.

### Empirical treatment of smear-negative disease

Where tuberculosis is suspected on clinical and radiological grounds but bacteriological proof is lacking, it is proper to start standard short-course chemotherapy while awaiting the results of bacteriological cultures [106,107]. If cultures prove positive, treatment should be completed; if cultures are negative, treatment should usually also be completed, except in the unusual event of a clinical and radiological response to treatment that is inappropriate (i.e. usually too fast or too complete). In such cases a simple bacterial pneumonia may have responded to rifampicin treatment; nevertheless such cases should be kept under review for 6 months if treatment is to be stopped.

### Standard 9-month chemotherapy

Chemotherapy for 9 months with rifampicin and isoniazid, supplemented by either ethambutol or streptomycin for the first 2 months, has a negligible relapse rate [23,108]. The dosage regimens are shown in Table 19.8. Satisfactory results have also been reported for 9 months of rifampicin and isoniazid alone [109,110], but such a regimen would be likely to fail in the presence of isoniazid-resistant organisms. Low relapse rates have been reported with a 9-month regimen of daily rifampicin and isoniazid for 1 month followed by 8 months of rifampicin 600 mg and isoniazid 15 mg/kg twice weekly [111].

### Non-compliant patients

The responsibility of the supervising clinician for ensuring that not only are tuberculosis patients prescribed appro-

**Table 19.8** Short-course chemotherapy: the 9-month regimen. (From Third East African/British Medical Research Council Study [98] and Tanzania/British Medical Research Council Study [99].)

Rifampicin	600 mg (> 50 kg) orally	}	for 9 months
	450 mg (< 50 kg) orally		
Isoniazid	300 mg orally		
Rifampicin and isoniazid to be given in combined preparation			
Ethambutol	15–25 mg/kg orally, or	}	for 2 months
Streptomycin	0.75 g i.m.		
	6 days out of 7		

Note: All orally administered drugs to be taken fasting 30 min before breakfast.

priate medication but also receive the medication and take it as prescribed for the full duration of treatment was pointed out as long ago as 1960 by John Crofton [112]. He said, 'I find myself, faced with a new patient, assuming that I can be sure of arresting his disease, but tending to forget that I can be quite certain to do so only if I take an immense amount of trouble over his chemotherapy, his bacteriology and his social and personal problems!' The consequences of failure to ensure compliance made news when a resurgence of tuberculosis in New York City in association with HIV infection, homelessness and the decline of tuberculosis control programmes was reported by Brudney and Dobkin in 1991 [113]. Smear-positive patients admitted to hospital were treated appropriately but on discharge to the community were lost to follow-up and did not comply with therapy; many were subsequently readmitted with progressive untreated or

relapsed disease. Failure to ensure treatment compliance or adherence may result also in inadvertent monotherapy, with the emergence of single drug-resistant and eventually multidrug-resistant organisms, such as was recently well documented in New York City [114]. Combined drug preparations should always be prescribed to these patients.

The solution to problems of patient compliance/adherence is apparently simple; if necessary, administration of every dose of treatment should be supervised (DOT). Detailed analyses of the sociocultural factors associated with patient non-compliance have been published [115,116]; in addition to poverty, homelessness and alcoholism, drug addiction, HIV-related illness and linguistic/ethnic difficulties have been identified. If treatment is to be effective in these groups, and it can be [117–119], then expenditure on health services with a major emphasis on education, incentives and the development of community health services to ensure the success of DOT is necessary. Tuberculosis health visitors, experienced nurses trained to work in the community, are the obvious professionals to undertake the task of tracing and treating individuals in the community.

Nardell [120] has outlined a sensible stepwise approach to the management of patients with tuberculosis. The steps, moving from least to most restrictive and, inevitably, from lesser to greater resource implications, are as follows.

- 1 Self-administration of daily standard short-course chemotherapy with monthly clinic visits; compliance can be checked by urine testing for rifampicin [26] or isoniazid [121].
- 2 DOT: daily, twice or thrice weekly, fully supervised in clinic, home or alternative site.
- 3 Voluntary long-term hospitalization in a specialized tuberculosis treatment unit or medical ward.
- 4 Compulsory, court-ordered, long-term hospitalization in a secure tuberculosis treatment unit or similar facility.

Most patients where compliance is likely to be a problem may be treated with standard daily four-drug therapy during an initial intensive phase of treatment in the hospital or clinic, with continuation therapy (for disease due to fully sensitive organisms) with twice- or thrice-weekly rifampicin and isoniazid for a total of 9 months [111] (see Table 19.1 for doses). More old-fashioned, but equally effective, therapy is with streptomycin 1 g and isoniazid 15 mg/kg twice weekly for 1 year [122,123]. Where disease is due to drug-resistant organisms, therapy may need to be prolonged for up to 2 years with untested combinations of drugs (see later).

The problems of compliance in the developed world pale into insignificance when compared with the treatment of tuberculosis under programme conditions in the developing world [124]. In one study in Bombay, 100

private doctors prescribed 80 different regimens most of which were inappropriate and expensive and only four of which conformed with the six regimens recommended in India's national tuberculosis programme [125].

## **Chemotherapy regimens for extrapulmonary tuberculosis**

The largest mycobacterial populations are seen in cavitating pulmonary tuberculosis, where 100% cure is possible with current short-course chemotherapy. It seems reasonable therefore, since these drugs diffuse well into all tissues, that the same short-course chemotherapy should be effective in all forms of extrapulmonary tuberculosis, where the mycobacterial population is smaller [126]. Remarkably few trials of such therapy have been reported. One group has reported a 97% success rate with no relapses following short-course chemotherapy in all forms of extrapulmonary tuberculosis [127].

### **Lymph node tuberculosis**

Standard 9-month chemotherapy has been shown to be effective in lymph node tuberculosis [128]. Standard 6-month short-course chemotherapy is similarly effective even when given intermittently [129]. Following termination of treatment in both this study and an earlier one of 18-month chemotherapy, increase in lymphadenopathy and even sinus formation occurred in a small percentage of patients [128,130]. This phenomenon, which may be due to tuberculin hypersensitivity, may occasionally require surgical intervention or corticosteroid therapy [131].

### **Bone and joint tuberculosis**

Surgical intervention is not usually necessary in skeletal tuberculosis, except in spinal tuberculosis where spinal cord compression is present or threatened [132]. The outcome in spinal tuberculosis is as good with 18-month ambulatory chemotherapy with PAS and isoniazid as it is in those immobilized with bedrest or plaster of Paris [133]. Anterior spinal fusion and débridement give no significant benefit over chemotherapy alone [134]. The results of short-course chemotherapy trials are awaited but there is no *a priori* reason to question the effectiveness of standard short-course chemotherapy in this situation.

### **Genitourinary tuberculosis**

Although success has been reported with 4-month chemotherapy for genitourinary tuberculosis [135], most chest physicians would prefer to adhere to proven therapy with standard short-course chemotherapy [136]. It is the

author's practice to prescribe prednisolone 40mg daily for 6 weeks with a graduated reduction in dosage thereafter in an attempt to prevent ureteric stricture formation [137]. Nevertheless, a few patients eventually require either ablative or reconstructive surgery [137].

### Central nervous system tuberculosis

The sequelae of tuberculous meningitis are so severe that prompt initiation of chemotherapy and corticosteroid therapy is mandatory. Rifampicin-based regimens are better than those not containing this drug, and at least three drugs should be used [138–140]. Rifampicin (15 mg/kg daily up to 600mg), isoniazid (15mg/kg daily, supplemented by pyridoxine 100mg) plus pyrazinamide in full dosage with either or both of ethambutol (15mg/kg daily up to 1g) and streptomycin (20–25mg/kg daily up to 1g) are recommended. Corticosteroids are believed to reduce neurological morbidity in tuberculous meningitis and have been shown to reduce mortality [141]. The recommended dosage is prednisolone 1 mg/kg daily. There is no indication for intrathecal therapy.

Hydrocephalus, if present, is usually of the communicating variety and may respond to therapy with acetazolamide and repeated lumbar puncture [142]. Obstructive hydrocephalus requires ventriculoatrial shunting [143,144].

The mortality of tuberculous meningitis is high at 20–25% even with presently available treatment [143,145–149]. Outcome is best in those who have no neurological abnormalities at presentation and worst in those with positive neurological findings, including disturbance of consciousness [145]. Tuberculoma of the brain is encountered uncommonly in the developed world but a report from India of 108 such patients documents the effectiveness of 9-month chemotherapy with rifampicin, isoniazid and pyrazinamide [150].

### Miliary tuberculosis

Treatment of miliary tuberculosis is with short-course chemotherapy for both adults and children, the dose of isoniazid being increased to 10–15 mg/kg. If the patient is severely ill or has tuberculous meningitis, then corticosteroid therapy should be added. In an adult a dose of 40mg prednisolone daily for 4–6 weeks is sufficient, reducing thereafter by 5mg every 5–7 days. In children the same type of regimen can be followed, with an initial dose of 2mg/kg daily for those under 2 years of age, 1.5mg/kg daily for those aged 2–10 years and 1mg/kg daily for those over 10 years. Recovery should be the rule in all patients receiving appropriate chemotherapy. Unfortunately, particularly in the elderly with cryptic disease, delays in diagnosis or failure to make a diagnosis may result in death.

## Chemotherapy regimens for primary tuberculosis

The management of the child whose only manifestation of tuberculosis is a positive tuberculin test has been discussed in Chapter 17. In any patient with a radiographically visible lesion, the rate of complication by disseminated tuberculosis in the younger age group, or by progressive pulmonary tuberculosis in those who have passed puberty, is such that chemotherapy is mandatory in all cases [151,152].

Where there is no suspicion that the infection is with a drug-resistant organism the preferred treatment is with rifampicin 10–20mg/kg (maximum 600mg) plus isoniazid 5mg/kg (maximum 300mg), both given on an empty stomach in a single daily dose. If primary resistance may be a problem, a third drug, either pyrazinamide (40mg/kg, maximum 2.0g) or PAS (250mg/kg), should be added until the sensitivities are known. Ethambutol should be avoided if possible in young children, who may not be able to report ocular toxicity. Chemotherapy should be continued for 9 months for a two-drug rifampicin-based regimen and for 12–18 months for other regimens, the longer period being for more severe and extensive lesions. Although isoniazid alone has been used to treat primary tuberculosis, the success rate is less than the 100% achieved with adequate combination chemotherapy and its use is not advised [152,153]. Side-effects from antituberculosis drugs appear to be no more common in children than in adults [154].

Following the initiation of chemotherapy the lymph node enlargement gradually subsides over a few months, although the parenchymal component may resolve more rapidly. Calcification may be the only residuum. Mechanical lesions due to bronchial complications may occasionally occur during chemotherapy, leading to radiological and clinical deterioration necessitating treatment with steroids (see later).

## Treatment in other special situations

Situations in which antituberculosis chemotherapy needs careful management are in the presence of renal or hepatic disease, in pregnancy, in small children and in HIV infection [22].

### Renal disease

The severity of renal impairment can be expressed in terms of creatinine clearance or the serum creatinine, the latter being less accurate unless corrected for age (Table 19.9). In the presence of renal impairment rifampicin is the safest drug to use in standard dosage, since in complete renal failure it is excreted entirely in the bile. Isoniazid in standard dosage is safe except in the presence of severe

**Table 19.9** Grading of severity of renal impairment.

Grade	Creatinine clearance (mL/min)	Serum creatinine (μmol/L)
Mild	20–50	150–300
Moderate	10–20	300–700
Severe	<10	>700

**Table 19.10** Dosage schedules for ethambutol in patients undergoing dialysis.

Dialysis programme	Creatinine clearance (mL/min)	Dosage
Regular	50–100	25 mg/kg twice weekly
	30–50	25 mg/kg twice weekly
Three times weekly		25 mg/kg
Twice weekly		40 mg/kg
Once weekly		90 mg/kg

renal disease, when only 200mg daily should be given, supplemented by pyridoxine 100mg daily to prevent peripheral neuropathy. Pyrazinamide may also be safely administered in standard dosage to patients with renal failure [137].

The aminoglycosides streptomycin and capreomycin should be given in reduced dosage if the creatinine clearance is less than 50mL/min and serum levels monitored to ensure trough levels (at 24 h) of less than 2μg/mL. A dose of 0.25g for 3 days per week may be adequate to sustain an appropriate serum concentration. If the patient is receiving regular dialysis, streptomycin 0.75g should be given 4–6 h before dialysis.

Cycloserine, PAS and ethambutol should be avoided in renal disease. If ethambutol is absolutely necessary, careful daily monitoring of serum levels to ensure that they do not exceed 5μg/mL is essential if eye toxicity is to be avoided. The interval between doses may need to be increased to 48 h; alternatively, a reduced daily dosage of 8–10mg/kg may be employed. For patients undergoing dialysis an appropriate schedule for ethambutol is shown in Table 19.10.

### Hepatic disease

Isoniazid, pyrazinamide and rifampicin may all cause hepatotoxicity in patients with liver disease, and liver function tests should be monitored closely in these groups. Rifampicin hepatotoxicity may be dependent on the concurrent administration of isoniazid [155]. Acute liver failure is the ultimate price for paying inadequate attention to the hepatotoxic potential of antituberculous

drugs [156]. Suggested guidelines for monitoring liver function have been published [28]. If major hepatotoxicity ensues with conventional short-course chemotherapy regimens and it proves impossible to resume therapy with any or all of rifampicin, pyrazinamide and isoniazid, then it may be possible to complete chemotherapy utilizing alternative triple therapy. Streptomycin, PAS or isoniazid and ethambutol for 3 months should be followed by 15 months of the two oral agents.

### Pregnancy

Pharmacological intervention of any kind during pregnancy always gives rise to debate. Of the available drugs, streptomycin is ototoxic to the fetus and should not be used during pregnancy. There is no evidence that isoniazid, ethambutol or PAS cause any kind of congenital malformation or are toxic in other ways to the fetus. Although known to be teratogenic in animals, rifampicin is not known to be teratogenic in the human [157]. Snider *et al.* [158] recommend that isoniazid and ethambutol be used to treat minor tuberculous disease in pregnancy and that rifampicin should be added if a third drug is warranted. It is the author's practice to employ the standard 9-month regimen with rifampicin, isoniazid and ethambutol in the initial 2-month phase followed by 7 months of rifampicin and isoniazid [22].

### Childhood

The basic principles of treatment of tuberculosis in childhood are essentially the same as for adults [159]; 9-month regimens containing at least isoniazid and rifampicin have been demonstrated to have a high rate of success in children. Because of difficulties in monitoring for ocular toxicity in young children, ethambutol is best avoided. Streptomycin or pyrazinamide are alternatives. The doses of standard antituberculosis drugs for children are shown in Table 19.1.

### HIV infection

Isolated case reports of failure of standard chemotherapy for tuberculosis in apparently, but not definitely, compliant patients with AIDS [160,161] have led to the inevitable questioning of the adequacy of such therapy for such patients [162]. Relapse is certainly commoner among HIV-positive than HIV-negative tuberculosis patients prescribed less-potent drug regimens in Africa [163,164]. With standard short-course chemotherapy, relapse rates are no more common in HIV-positive than in HIV-negative patients if the continuation phase of treatment is prolonged to give a total duration of chemotherapy of 9 months [165,166]. The rate of sputum culture conversion is similar in both groups. Antituberculosis chemotherapy

combined with zidovudine therapy is safe and well tolerated [167].

### Drug resistance and the management of disease due to drug-resistant organisms

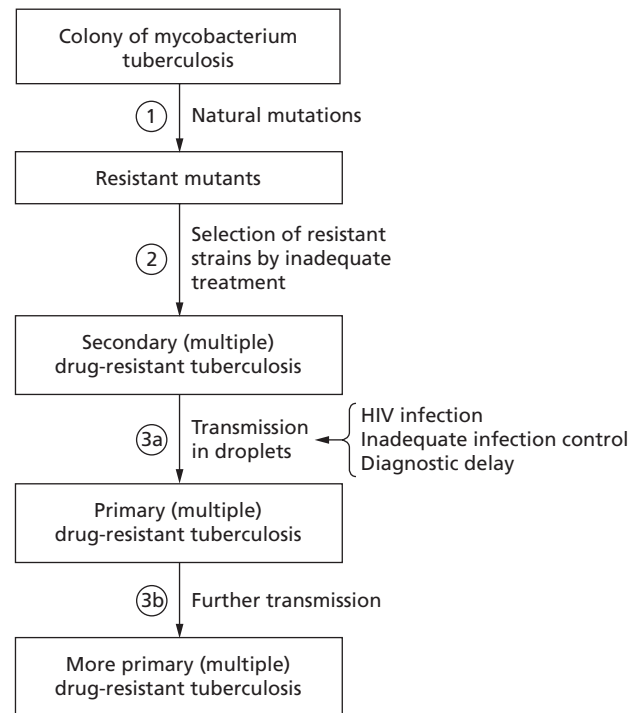

It took the emergence of multidrug-resistant tuberculosis in New York City [114] to fully focus the professional mind on the problems of preventing drug-resistant tuberculosis. The problem is not new to the world—reports from some countries indicate resistance rates of 37% to rifampicin and 55% to isoniazid [168]—but is relatively new as a major problem in the developed world. Rieder [169] and others [170] have emphasized that the present problems with drug-resistant tuberculosis are due to complacency over previously well established principles.

The simple observation that it is not enough to prescribe the microbiologically appropriate drugs but that it is also necessary to ensure that the drugs are taken for the prescribed duration [112], however difficult that may be, has been forgotten. If therapy composed of single drug formulations is left unsupervised in the hands of the poor, the homeless, the addicted and the HIV infected, monotherapy may result. Monotherapy may lead to acquired resistance and inadequately treated disease will result in the transmission of primarily resistant disease to others. The cycle may repeat and multidrug resistance, as reported from New York City, emerges.

If it can happen in New York City, there can be little wonder that drug resistance is a problem worldwide. Of increasing concern are the possible worldwide consequences of introducing short-course chemotherapy with the primary antituberculosis drugs, i.e. the World Health Organization's DOTS programme [171]. Reassuringly, in Tanzania the programme, which *must* incorporate rifampicin in combination with isoniazid, has not led to any increase in rifampicin resistance [172]. The worst possible scenario [172], one in which tubercle bacilli become increasingly resistant to multiple drugs resulting effectively in a return to the prechemotherapy era of tuberculosis with 50–80% mortality rates, will only be avoided if the long-established principles of treating tuberculosis are rigidly observed. At present, this means considering the need for DOT for every patient [120].

### Development and spread of drug-resistant tuberculosis

The pathways involved in the development and spread of multidrug-resistant tuberculosis are shown in Fig. 19.7 [173]. Mutant bacilli resistant to single drugs exist in nature (as described earlier) and are selected by inadequate treatment. Inadequate treatment may involve ingestion of only one drug (direct monotherapy) or ingestion of

**Fig. 19.7** The three stages in the development and spread of multidrug-resistant tuberculosis. A fourth contribution to the problem comes from migration of patients with primary and secondary resistance into the control area. (From Lambregts-van Weezenbeek & Veen [173] with permission.)

a combination of drugs only one of which the strain is sensitive to (indirect monotherapy). Secondary (or acquired) resistance to one drug results. New mutations in this growing bacillary population eventually lead to multidrug resistance if inadequate treatment is continued.

Tuberculosis patients with secondary drug-resistant tuberculosis may infect others who are then said to have tuberculosis that demonstrates primary resistance. Such transmission is facilitated by HIV infection, where disease development and progression seem more rapid [174], by inadequate infection control procedures (particularly in healthcare settings) and by diagnostic delays. Primary or secondary drug-resistant tuberculosis may also be imported, particularly from countries with a high prevalence of disease where control programmes may be inadequate. Primary drug resistance, like secondary drug resistance, may be transmitted to others thus spreading drug-resistant disease within the community.

The extent of drug-resistant tuberculosis can only be determined by laboratory surveillance of isolated strains. In the developed world all isolated strains should have their drug sensitivity patterns determined [174]. In the developing world, with fewer resources, periodic surveys may serve as a marker for developments in the community [175].

### Interventions of value in preventing the emergence of drug resistance

In most developed countries standard short-course chemotherapy with four drugs is continued until drug sensitivity patterns are known. Since drug resistance, even to one drug, is uncommon (<2% in the UK), indirect monotherapy is unlikely to occur in the initial phase and the continuation phase can be planned with knowledge of any detected drug resistance, ensuring that the disease is treated with at least two drugs to which the organism is sensitive. Where the possibility of multidrug resistance is high, e.g. a relapsed patient with previous suspect chemotherapy, an immigrant from a country where drug resistance is common or a contact of a known case of multidrug-resistant tuberculosis, then treatment should be initiated with *at least three drugs* to which the bacillus is known or likely to be sensitive. If the patient's clinical condition permits, it is sometimes wise to withhold therapy until full drug sensitivity details are available in order to allow informed treatment planning. All therapy should be supervised and should continue until sputum cultures have been negative for at least 6 and preferably 12 months. In any country the standard treatment guidelines should be based on an awareness of the drug-resistance pattern of disease in the community.

Education of the medical and paramedical professions in all aspects of the diagnosis and management of tuberculosis needs to be maintained or re-emphasized. In countries where disease incidence is low, advice from tuberculosis specialists should be sought as soon as the diagnosis is made and if any doubt about appropriate management exists.

A strong case can be made for restricting the use of rifampicin to tuberculosis alone and then only when supervised. Where at all possible, rifampicin should only be prescribed in the form of combination tablets (plus isoniazid with or without pyrazinamide) but these tablets must be of proven bioavailability [176].

Finally, efforts to improve patient compliance/adherence must be pursued as described above. Such measures may include education, free treatment, treatment incentives and DOT, which in itself has been shown to decrease

the frequency of drug-resistant disease in the community [177].

### Treatment of drug-resistant disease

The essentials of treatment have been outlined above. Detailed practical advice has been published [178,179]. The essence of success is to treat with at least two and preferably three drugs to which the organism is known or believed to be sensitive until sputum cultures have been negative for at least 6 and possibly 12 months. Where disease is intractable, surgical resection may be of value [180]. In hospitalised patients precautions to prevent spread of disease have been discussed in Chapter 16 (pp. 478–9).

### Corticosteroid therapy in tuberculosis

The use of corticosteroids in the management of patients has recently been extensively reviewed [181,182]. It must be emphasized that corticosteroids should never be given to patients with tuberculosis unless they are receiving adequate antituberculosis therapy. The main indications for corticosteroid therapy in tuberculosis are as follows:

- 1 in very seriously ill patients to buy time for chemotherapy to become effective [183];
  - 2 to control drug hypersensitivity reactions [184];
  - 3 in tuberculosis of the serous sacs, i.e. pericarditis [185], peritonitis and pleural effusion to prevent fibrosis and adhesions and to hasten absorption of fluid;
  - 4 in tuberculous meningitis to prevent morbidity and mortality due to adhesions, particularly in stage II and III disease [186];
  - 5 in genitourinary tuberculosis to prevent the development of ureteric strictures [137];
  - 6 occasionally for the suppression of lymph node enlargement during chemotherapy, e.g. where mediastinal lymph nodes are causing bronchial obstruction or, occasionally, for the management of tuberculous endobronchitis [187].
- The usual dose of prednisolone is 40 mg daily in adults if rifampicin is being used since it reduces the bioavailability of prednisolone [35]. Prednisolone is usually given for 6 weeks reducing gradually thereafter, e.g. over 4 weeks. Prednisolone should never be prescribed for tuberculosis in the absence of adequate chemotherapy.

# OPPORTUNISTIC MYCOBACTERIAL DISEASE

A. GORDON LEITCH

Pulmonary disease resulting from *Mycobacterium tuberculosis* complex infection is often called classical pulmonary tuberculosis. *M. tuberculosis* is an obligatory parasite, being unable to exist for long outside the body of the host. In contrast, other species of mycobacteria exist free in nature and are well-recognized causes of disease in humans and animals [1–3]. Pulmonary disease is most often due to infection with the *M. avium-intracellulare* complex (i.e. *M. avium*, *M. intracellulare* or *M. scrofulaceum*), *M. kansasii*, *M. malmoense* or *M. xenopi*. However, at least 20 other mycobacteria may cause pulmonary disease (Table 20.1) and, as techniques for isolating and characterizing these mycobacteria improve, the numbers are likely to increase [4].

An assortment of names has been employed to describe the mycobacteria that cause lung disease other than classical pulmonary tuberculosis. These include atypical, anonymous, tuberculoid and non-tuberculosis mycobacteria, as well as mycobacteria other than tuberculosis. The designation 'opportunistic' mycobacteria has been employed since disease occurs sporadically and often in patients with pre-existing lung disease or suppressed immunity [5].

This chapter describes the epidemiology, bacteriology, clinical and radiological features and management of pulmonary disease caused by the most frequently encountered opportunistic mycobacteria, and lays down guidelines for the management of disease due to those species less frequently encountered.

## Epidemiology

### Distribution and extent of disease

Pulmonary disease caused by opportunistic mycobacteria (designated 'atypical') was first described in several large series of patients from the southern USA in the 1950s [6–8]. The patients affected were epidemiologically quite distinct from patients with pulmonary tuberculosis. Even at this early stage it was appreciated that they were older and

frequently afflicted with other chronic lung diseases, such as bronchiectasis, pneumoconiosis and healed tuberculosis. Positive Mantoux tests were less common in this group of patients and close contacts did not appear to have been infected.

Although then, as now, opportunistic mycobacterial disease was not a notifiable condition, it soon became apparent in the USA that disease due to *M. avium* complex was most common in the rural south-eastern states, whereas *M. kansasii* was a more common cause of disease in the central states [9]. This clinical observation was borne out by skin-test surveys utilizing tuberculin and opportunistic mycobacterial antigen: infection by opportunistic mycobacteria appeared to be particularly common in the rural areas of the south-eastern USA [10,11].

Subsequent reports based on laboratory isolates of opportunistic mycobacteria in the USA have indicated that they comprise 30% of all mycobacterial isolates in the USA and that *M. avium* complex is the most frequently detected [12]. A more recent survey in the USA estimates the prevalence of opportunistic mycobacterial disease at 1.8 per 100 000 population of which 1.1 per 100 000 is due to *M. avium* complex infection [13]. In western Europe, in contrast, *M. kansasii* is the commonest species encountered in general [14], although specific regional and national variations occur; in Scotland, for example, *M. avium* complex and *M. malmoense* predominate [15].

The advent of human immunodeficiency virus (HIV) infection has dramatically altered the epidemiology of opportunistic mycobacterial infection. *M. avium* is now recognized as one of the more common opportunistic infections in patients with AIDS in the USA [16,17], with up to 50% of patients having disseminated *M. avium* complex disease at the time of death [18]. More than 95% of these infections are due to *M. avium* rather than *M. intracellulare* serotypes [19]. Opportunistic mycobacteria other than *M. avium* may cause disease in the HIV setting; in south-east England, for example, although *M. avium* infections predominate in this population, a

Species	Growth rate	Runyan group	Usual disease
<i>M. tuberculosis</i> *	Slow	TB complex	Classical tuberculosis
<i>M. bovis</i>	Slow	TB complex	Classical tuberculosis

\* Important human pathogen.  
† Depending on culture conditions.

substantial minority of disease is caused by other opportunistic mycobacteria, of which *M. xenopi*, *M. kansasii* and *M. gordonae* are the most common [20].

Sources of infection

Most opportunistic mycobacteria may be isolated from water and soil [21,22]. In the USA, *M. avium* complex flourishes in natural waters, particularly in the south-east [23]. *M. kansasii* and *M. xenopi* have been isolated from tap water [24], even in hospitals, where cases of pulmonary disease have resulted [25]. *M. malmoense* has yet to be isolated from environmental sources, the difficulty in doing so perhaps reflecting its fastidious cultural characteristics.

The presumption must be that opportunistic mycobacterial pulmonary infection and disease result from the inhalation of, presumably aerosolized, organisms from the environment. Although similar mycobacteria-bearing aerosols are likely generated as a result of coughing in patients with disease, to all intents and purposes transmission of disease from humans or animals to other humans does not occur. Opportunistic mycobacterial pulmonary disease is *not infectious* and, unlike *M. tuberculosis* disease, has no important public health consequences; in particular, contact tracing, chemoprophylaxis, etc. are not required.

Ingestion of opportunistic mycobacteria is considered to be the likely cause of cervical lymphadenopathy in children. Direct inoculation of opportunistic mycobacteria, e.g. *M. marinum*, in water or from other material

Table 20.1 Mycobacteria causing human lung disease.

is likely to be the source of infection for patients with superficial cutaneous or soft-tissue infection.

Bacteriology

Classification

A relatively simple classification was introduced by Runyan in 1959 [26]. This depended on the cultural characteristics of the mycobacterium as shown in Table 20.2. Organisms were either slow growers (groups I–III) or fast growers (group IV); the slow growers were pigmented on exposure to light (I), pigmented in light and dark (II), or only weakly pigmented or non-pigmented (III). While still serving as a useful guide to the likely clinical relevance of an isolate, subsequent taxonomic advances, utilizing a wide range of techniques of characterization, have led to this scheme no longer being widely used. Classification of species can usually be obtained by applying a range of simple biochemical and cultural tests, such as temperature range, pigment production, oxygen preference and Tween-80 hydrolysis. More rapid methods for species identification are currently being developed and/or applied, including thin-layer chromatography, gas–liquid chromatography and high-pressure liquid chromatography, and the use of specific DNA probes, currently available for *M. avium* complex, *M. kansasii* and *M. gordonae*. The number of opportunistic mycobacterial species identified is continually growing [4,27]; most of those relevant to human pulmonary disease are shown in Table 20.1.

**Table 20.2.** Runyan classification of mycobacteria.

---

Group I (photochromogens): slow-growing, pigmented on exposure to light
Group II (scotochromogens): slow-growing, pigmented in light and dark
Group III (non-photochromogens): slow-growing, weak or no pigmentation
Group IV (rapid growers): colonies within 7 days at 24°C and 37°C

---

### Isolation and culture methods

The culture and identification of opportunistic mycobacteria is a procedure that should be reserved for the highest level laboratories. The simple digestion, decontamination and staining procedures used for *M. tuberculosis* have also proved useful for the other mycobacteria. Both the Ziehl–Nielsen stain and the fluorochrome procedure identify the presence of opportunistic mycobacteria in clinical material. Microscopy does not differentiate them from tuberculous mycobacteria with the exception of *M. kansasii* organisms, which are often larger with a more beaded appearance.

Almost all opportunistic mycobacteria with the exception of *M. haemophilum* can be cultured on conventional *M. tuberculosis* media, including the radiometric Bactec system (see Chapter 17). Growth is usually detected within 2–4 weeks on solid media and in 1 week with the Bactec system. It may be helpful to extend the duration of incubation to detect growth of some opportunistic mycobacteria, e.g. *M. malmoense* grows very slowly (mean 54 days, range 31–87 days) compared with all other mycobacteria (mean 30 days, range 10–84 days) [28].

### Antimycobacterial drug susceptibility testing

It is generally recognized that the application of the techniques of *in vitro* drug susceptibility testing relevant to the management of pulmonary tuberculosis is frequently, if not always, inappropriate in the context of opportunistic mycobacterial infection. Many of these mycobacteria may be drug resistant *in vitro* but, judged by clinical response, drug sensitive *in vivo* [29–31]. Most clinicians have experience of patients with pulmonary disease whose clinical condition is improving on standard antituberculous chemotherapy (rifampicin, isoniazid, ethambutol, pyrazinamide) but which deteriorates when chemotherapy is modified, apparently appropriately, when the results of drug susceptibility testing become available, only to improve again when the apparently ineffective initial therapy is reinstated.

A move towards recognizing the potentially confusing nature of drug susceptibility test results has been made by the American Thoracic Society [32]. They recommend that

routine susceptibility testing does not provide useful clinical information and should not be performed for *M. avium* complex or for the rapid growers *M. marinum*, *M. fortuitum* and *M. chelonae*. Drug susceptibility testing should be retained for *M. kansasii*, *M. xenopi*, *M. malmoense* and other less common mycobacteria. It is important to stress that there is no evidence to justify a conclusion that chemotherapy for such infections should necessarily be based on, or altered by, the results of *in vitro* susceptibility testing. It remains the case that with such infections the patient is the site of the susceptibility test, and current best practice is based more on clinical experience than laboratory-derived evidence. Fortunately most disease due to *M. kansasii*, *M. xenopi* and *M. malmoense* appears to respond to treatment with rifampicin and ethambutol with or without other drugs (see below).

A healthy degree of scepticism about *in vitro* susceptibility test results for opportunistic mycobacteria is warranted by the poor correlation of such results with response to treatment. The limitations of applying *M. tuberculosis* susceptibility testing to these mycobacteria may well be responsible. Some sense may have been generated by the observation that strains of *M. avium* complex, *M. xenopi* and *M. malmoense* which were resistant to both ethambutol and rifampicin when tested separately to each drug were sensitive in a minority, a majority and *in toto*, respectively, when susceptibility was tested to the two drugs combined [33].

In like fashion the full meaning of susceptibility test results with the newer drugs, such as the fluoroquinolones (e.g. ciprofloxacin), the macrolides (e.g. clarithromycin) and the rifamycins (e.g. rifabutin), and their relation to clinical effects remains to be determined.

### Diagnostic criteria

Since opportunistic mycobacteria are capable of colonizing the bronchial tree without causing disease, their isolated culture from sputum is not necessarily of pathological significance. Conventional criteria for the diagnosis of disease therefore require the presence of infiltrative lung disease (for which other causes have been effectively excluded) and isolation of the mycobacteria repeatedly from sputum. Culture of the organism from lung biopsy, bronchoalveolar lavage or pleural fluids or blood culture is of greater diagnostic significance than an isolated sputum culture. The American Thoracic Society [32] has agreed the following criteria for the diagnosis of opportunistic mycobacterial pulmonary disease.

1 For patients with a cavitary infiltrate on the chest radiograph when:

- (a) two or more sputa (or sputum and a bronchial washing) are positive for acid-fast bacilli and/or result in moderate to heavy growth of opportunistic mycobacteria on culture;

(b) other reasonable causes for the disease process, e.g. fungal disease, malignancy, tuberculosis, have been excluded.

Approximately 90% of patients with *M. kansasii* disease and 75% of patients with *M. avium* disease will have cavitary infiltrates and disease will be diagnosed by these criteria [34].

2 In the presence of a non-cavitary infiltrate not known to be due to another disease, opportunistic mycobacterial pulmonary disease is present when:

- (a) two or more sputa (or sputum and a bronchial washing) are positive for acid-fast bacilli and/or result in a moderate to heavy growth on culture;
- (b) failure of sputum cultures to convert to negative with either bronchial hygiene or 2 weeks of specific antimycobacterial therapy;
- (c) other reasonable causes for the disease have been excluded.

The second criterion is presumed to exclude colonization rather than a disease state. *M. chelonae* lung disease is usually non-cavitary and would be diagnosed by these criteria. A presumed colonization state should not preclude the patient from continuing observation for clinical symptoms and pulmonary findings; the indolent nature of some infections may prevent early diagnosis and the disease process may eventually progress.

3 In patients with low numbers of organisms on sputum culture and/or where another disease process cannot be excluded, a lung biopsy is often required for diagnosis [35]:

- (a) if the lung biopsy yields the organisms and shows characteristic mycobacterial histopathological features, no other criteria are needed;
- (b) if the biopsy yields no organisms but shows mycobacterial histopathological features in the absence of a prior history of other granulomatous or mycobacterial disease then (i) presence of two or more positive cultures of sputum or bronchial washings and (ii) exclusion of other reasonable causes for granulomatous disease are required.

These criteria should only be used as a guide in dealing with individual patients. Sometimes repeated positive cultures are obtained when old fibrotic lung disease has simply been colonized by the organisms. At the other extreme, progressive lung disease and evident illness may require treatment as soon as the first culture is obtained.

The diagnosis depends on the laboratory, which obtains its first clues from the cultural characteristics of the organism and its pattern of drug susceptibility. Subsequent identification requires techniques beyond the scope of most microbiological laboratories and cultures should be sent to a supraregional or national mycobacteria reference laboratory.

## Clinical features and radiology

### Clinical features

Most patients are middle-aged or elderly males and most have pre-existing lung disease, usually chronic bronchitis and emphysema or old healed tuberculosis [29–31,36–39]. The patient may have worked in a noxious or dusty environment or even have pneumoconiosis [40]. Sometimes, the patient is immunosuppressed by disease or drugs; the possibility of HIV infection, particularly in the young, must be constantly remembered. Chronic pulmonary disease resembling pulmonary tuberculosis is the most common presentation, with symptoms of cough, sputum, haemoptysis, weight loss, malaise, fever and increasing dyspnoea. Acute illness at presentation is uncommon and the picture is usually one of a subacute or chronic illness.

### Radiology

The radiological features are typically upper zone fibrosis with cavitation (Fig. 20.1), although miliary spread is occasionally seen in the immunosuppressed. The appearances may be impossible or difficult to distinguish from classical tuberculosis or from chronic fibrosis with bronchiectasis due to, for example, allergic alveolitis, pulmonary aspergillosis or sarcoidosis. Occasionally the appearances may be of centimetre-sized nodular or patchy irregular infiltrates in both lungs [35]. Attempts to usefully differentiate opportunistic mycobacterial diseases from each other and from tuberculous mycobacterial disease on the basis of radiological appearances have failed [41,42].

### Differential skin testing

At present species-specific skin-test antigens are neither sufficiently standardized nor specific to have any place in the diagnosis of opportunistic mycobacterial disease.

## Management

### *Mycobacterium avium-intracellulare* disease

As already indicated, *M. avium-intracellulare* is resistant to most, if not all, conventional antituberculosis drugs on susceptibility testing. Routine susceptibility testing for this organism is not recommended [32]. Most recommended chemotherapy regimens for disease due to this organism are based on published series of treated cases. Controlled clinical trials have not been reported to date.

### Pulmonary disease

A small number of patients with *M. avium* complex lung

**Fig. 20.1** Chest film of a patient with chronic airflow obstruction and infection with *M. kansasii*. Note the fibrosed and cavitated right upper lobe.

disease may be relatively asymptomatic and have stable radiographic appearances. They may be managed by observation only, even if their sputum clears. However, the majority of patients have significant symptomatology and/or evidence of progressive or extensive radiological disease. Recommended initial therapy for *M. avium* complex disease consists of isoniazid 300 mg, rifampicin 600 mg, ethambutol 25 mg/kg for 2 months and 15 mg/kg thereafter, with streptomycin for the first 3–6 months (see Nallace *et al* [32] for dosage regimens). Therapy is recommended for 18–24 months and for at least 12 months after sputum culture conversion. Several clinical trials using the four-drug regimen have shown sputum conversion rates of up to 80% [29,43–45].

Sputum smear and culture should be assessed monthly, at least initially, following the start of treatment to assess response. Occasional positive sputum cultures after apparent sputum conversion do not necessarily indicate treatment failure or relapse. Definite relapses after discontinuation of therapy are common, averaging 20% or higher even with the recommended four-drug regimen [44].

Patients who fail to convert their sputum cultures after 12 months of therapy should probably have their treatment discontinued. If stable, then observation is in order, but if they have clearly progressive symptomatic disease then an alternative multidrug regimen incorporating cycloserine (250 mg twice daily), ethionamide (250 mg

twice or thrice daily), clofazimine (100–200 mg daily), a rifamycin such as rifabutin (600 mg daily), a fluoroquinolone such as ciprofloxacin (1000–1500 mg daily) or a macrolide such as clarithromycin (1000–2000 mg daily) may be successful [46,47].

Many, if not most, patients will have been started on standard antituberculosis chemotherapy (rifampicin, isoniazid, ethambutol, pyrazinamide) when sputum smear positivity for acid-fast bacilli has been detected. If clinical progress is satisfactory at the time *M. avium* complex is confirmed by sputum culture testing, it would be reasonable to continue treatment with rifampicin, isoniazid and ethambutol for 18–24 months as per the above guidelines.

Where disease is progressive in spite of treatment, or sufficiently localized and where lung function permits, surgical resection under chemotherapeutic cover should be considered. Resection may result in cure [48,49]. Resected solitary pulmonary nodules that prove to be due to *M. avium* complex disease require no further therapy in the absence of evidence of other *M. avium* complex disease or immunosuppression.

#### *Clarithromycin*

Clarithromycin (1000–2000 mg daily) has been shown to be an effective single agent in the treatment of *M. avium* complex disease in the non-immunocompromised host

[50,51]. Clarithromycin resistance develops in 16% of isolates [50]. The potential for relapse remains to be fully assessed. Clarithromycin-sensitive *M. avium* complex strains contain  $10^{-8}$  to  $10^{-9}$  resistant mutants and development of drug-resistant disease and relapse is due to multiplication of these pre-existing mutants [52]. Given its efficacy in not only non-HIV-related but also HIV-related *M. avium* complex disease (see below), clarithromycin is clearly a powerful additional drug in the armamentarium available for treating this disease. Clinical trials incorporating clarithromycin in treatment regimens for *M. avium* complex disease have been started and the results are awaited.

### **Disseminated *Mycobacterium avium* complex disease**

Disseminated *M. avium* complex disease is usually a late opportunistic infection in severely immunosuppressed patients with AIDS [53]. Multidrug regimens similar to those used for pulmonary disease (but including clofazimine) have resulted in symptomatic and clinical improvement in most patients [54–57]. Clarithromycin is extremely effective against *M. avium* [58] and monotherapy with this drug in AIDS patients with disseminated disease abolishes bacteraemia in 99%; however, relapse occurs due to the emergence of clarithromycin-resistant organisms [53]. It seems likely that clarithromycin will emerge as one of the most important, if not the most important, antibiotic in treating disseminated *M. avium* complex disease. As in the early developmental days of tuberculosis chemotherapy, it will be necessary to determine by appropriate trials of multidrug therapy incorporating clarithromycin which combinations are most effective in preventing the emergence of drug-resistant organisms. At present a combination of rifampicin (or rifabutin) plus ethambutol, ciprofloxacin, isoniazid and clarithromycin might theoretically be recommended but the results of clinical trials are awaited.

### ***Mycobacterium kansasii***

*M. kansasii* disease that is positive on sputum and chest radiography progresses clinically and radiographically if no treatment is given [59]. Treatment of pulmonary disease is therefore mandatory. Current American Thoracic Society recommendations are for 18 months of combined treatment with isoniazid (300mg), rifampicin (600mg) and ethambutol (15mg/kg) [32]. Long-term relapse rates with rifampicin-based therapy are low [39]. A recent study from Spain [60] suggests that therapy with rifampicin, isoniazid and ethambutol can be abbreviated to 12 months (ethambutol given for the first 6 months) without increasing the risk of relapse. A UK study has also shown effective treatment of *M. kansasii* disease with a 9-month rifampicin and ethambutol regimen [61], although

the relapse rate, which may have been 9.7%, can be regarded as unacceptably high [62]. Until these studies are confirmed the standard regimen of rifampicin, isoniazid and ethambutol for 18 months is recommended.

Patients with organisms resistant to rifampicin as a result of previous therapy have been shown to respond well to oral therapy with high-dose isoniazid (900mg), pyridoxine (50mg), ethambutol (25mg/kg) and sulfamethoxazole (sulphamethoxazole) (3g) for 18–24 months, combined with daily amikacin or streptomycin for 2–3 months given intermittently thereafter for a total of 6 months [63]. Subsequent studies from the same group [64] have shown 90% sputum conversion in patients with rifampicin-resistant infection when treated with four-drug regimens selected on the basis of *in vitro* susceptibilities.

Disseminated *M. kansasii* disease is the second most common opportunistic mycobacterial infection in AIDS patients [65]. In the absence of suitable guidelines, standard chemotherapy should be employed.

### ***Mycobacterium mageritense***

Rifampicin and ethambutol appear to be the most important drugs for inclusion in chemotherapeutic regimens for disease due to *M. mageritense*. Treatment for 18–24 months with ethambutol- and rifampicin-containing regimens fared better than other regimens in retrospective studies [15,31,36]. The organisms may be sensitive *in vitro* to ciprofloxacin and/or clarithromycin but their role *in vivo* remains to be determined. Many patients are elderly with quite severe pre-existing lung disease [66] and death may ensue before the infection is eliminated, not necessarily because of the infection.

### ***Mycobacterium xenopi***

*M. xenopi*, so named because it was first isolated from a toad, also lives in water. Its existence in the tap water used to clean and consequently contaminate fiberoptic bronchoscopes led to an apparent epidemic of disease in Michigan, Ontario [67]. The organism shows very variable patterns of drug susceptibility *in vitro* and is often resistant to rifampicin, isoniazid and ethambutol [68]. Moreover, resistance patterns may change on sequential culture. *In vitro* drug susceptibility tests do not always predict *in vivo* clinical response [30,38]. On presently available evidence [30,38,69] treatment with ethambutol, isoniazid and rifampicin for at least 2 years is recommended. Relapse of *M. xenopi* infections, even when the organisms are sensitive *in vitro* to rifampicin and ethambutol, is common [70] if the duration of therapy is inadequate.

### ***Mycobacterium fortuitum***

Pulmonary disease due to this rapidly growing mycobacterium is uncommon. *M. fortuitum* is usually susceptible *in vitro* to amikacin, ciprofloxacin, sulphonamides, imipenem and doxycycline [71]. Such infections have been successfully treated with ciprofloxacin-containing regimens [72,73].

### **Other opportunistic mycobacteria**

The most commonly encountered opportunistic mycobacterial infections have been discussed above. As a general rule discordance between *in vitro* tests of drug susceptibility and *in vivo* therapeutic response as clinically assessed is not uncommon. This should always be borne in mind when considering treatment interventions and modifications in the management of these mycobacterial infections.

Most patients with opportunistic mycobacterial disease are likely to have been started on treatment with standard

quadruple antituberculous chemotherapy (rifampicin, isoniazid, ethambutol, pyrazinamide) prior to the isolation, characterization and drug susceptibility testing of their infecting mycobacterium. As a general rule if the patient is improving clinically on standard therapy, then this should not be modified *whatever* the results of *in vitro* susceptibility testing. Treatment should be continued for at least 18 months and preferably 2 years with all four drugs.

If there has been no clinical response or deterioration has occurred then at least two additional drugs, preferably those to which the organism is sensitive *in vitro*, should be added to the regimen. Ciprofloxacin and clarithromycin are likely to play an important role in this scenario, although reports supporting this role are still awaited. Treatment should be continued for at least 18–24 months. When treating opportunistic mycobacterial disease it is always important to consult not only the literature but also those with accumulated experience of treating the disease and also, and certainly not least, the laboratory mycobacteriologist.

# ACTINOMYCOTIC AND FUNGAL DISEASES

ANTHONY SEATON

This chapter follows the traditional practice of considering together, albeit incorrectly, the higher bacterial actinomycetes and the fungi. The practice is justified by the similarities of the diseases with which they may be associated and, in some respects, their morphology. However, the differences between them are large in biological terms and, clinically, in terms of response to chemotherapeutic agents. Also discussed is the increasingly important organism *Pneumocystis carinii*, now generally agreed to be classifiable as a fungus.

## Actinomycetes

The bacterial order Actinomycetales includes the familiar Mycobacteriaceae (see Chapters 16–20), the Actinomycetaceae and the Nocardiaceae, together with the Thermomonosporaceae and Thermoactinomycetaceae (Table 21.1).

The Actinomycetaceae include the genera *Actinomyces*, *Actinobacillus* and *Arachnia*. *Actinomyces* spp. are slow-growing, Gram-positive filamentous organisms that differ from fungi in lacking a nuclear membrane, having no chitin in their cell walls and reproducing by fragmentation of their filaments rather than by spore formation. Most strains, including *Actinomyces israelii*, are anaerobic or microaerophilic and grow best at 37°C, forming mature heaped-up colonies within about 1 week. *Arachnia* spp. are very similar in cultural characteristics but produce smoother colonies. *Nocardia* spp. are filamentous, weakly Gram-positive organisms with a tendency to break up into coccobacillary forms. They grow aerobically over a wide temperature range and growth is promoted in 10% carbon dioxide. Growth may be slow and the pigmented colonies may be obscured by faster-growing organisms.

*Nocardia* spp. are soil saprophytes, living in decaying organic matter and are normally introduced into humans or animals by inhalation of particles in dust or by trauma and wound infection. In contrast *Actinomyces* and *Arachnia* spp. live as saprophytes in the mouths of humans and animals, causing infection as a result of oral trauma or

disease, or following aspiration of infected matter into the lungs.

## Fungi

Fungi are a group of spore-bearing, often filamentous, organisms that lack chlorophyll and therefore obtain their food by either a saprophytic or a parasitic existence. Most live by breaking down dead organic matter and, in their turn, they or their spores may provide food for other organisms such as amoebae and insects. They reproduce by producing spores, either sexually or asexually, or by budding or fragmentation.

The classification of fungi is complex and of little relevance to an understanding of their pathogenic effects. Confusion arises partly from their pleomorphism, i.e. their ability to produce two or more phenotypes from one genotype. In the sexual form the fungus is said to be in a perfect state, while in the asexual form it is said to be in an imperfect state. Many fungi, including several of medical importance, were first described and named in the imperfect state and were then found to produce, under appropriate cultural conditions, a sexual form that had a different name. Fungal taxonomy now uses the name of the perfect form, although in medical terminology the original imperfect form names have been retained. Moreover, a whole group of fungi, the fungi imperfecti, are classed together not on morphological or biochemical grounds but because they have no known perfect form; this group includes *Aspergillus*, *Paracoccidioides* and *Penicillium*. An abbreviated classification of some fungi of medical importance is given in Table 21.2.

## Growth and reproduction of fungi

Fungi have nuclei and cell walls [1]. In filamentous organisms the latter generally consist of polysaccharide, glycoprotein and chitin [2]. The filament elongates and branches, and is often divided incompletely by the development of septa. The filament is called a hypha, and a

Family	Genus	Disease
Actinomycetaceae	<i>Actinomyces</i> <i>Arachnia</i> <i>Propionibacterium</i>	Actinomycosis

\* *Blastomyces* is the imperfect form.

† *Histoplasma* is the imperfect form.

‡ *Candida* is the imperfect form.

§ *Cryptococcus* is the imperfect form.

mass of hyphae a mycelium. The hypha absorbs nutrients and growth occurs from its tip; spores may develop on a specialized hyphal extension, the conidiophore. In their development they assume the cell wall of the hypha but take a roughly spherical or ovoid shape. They are adapted to survival in adverse conditions and are dispersed by air, water or animals. Germination of spores occurs in appro-

priate conditions and is associated with splitting of the cell wall and emergence of a germ tube. The process initiating germination is ill understood, but requires sufficient moisture and oxygen and involves uptake of water by the spore. The spore swells and its metabolic rate increases.

Many fungi exist in a unicellular form, when they are known as yeasts; most of these also exist in a mycelial form, making life difficult for taxonomists. The yeast cell wall consists mainly of mannans and glucans, with less chitin than that of filamentous fungi. Yeasts reproduce by budding, the bud arising from the inner layer of the cell wall. *Candida* and *Cryptococcus* are familiar pathogenic yeast forms.

Fungi are of considerable importance to humans in both a positive and a negative sense. Their metabolic products are exploited widely in biotechnology, the best-known being alcohol and penicillin. These, together with such products as the cephalosporins, citric and gluconic acids, glucose oxidase and catalase, form the basis of a substantial industry. On the other hand, many are plant parasites that damage food crops, for example the potato blight *Phytophthora* has had a major effect on populations. Toxic materials produced by fungi include the carcinogen aflatoxin. In addition many fungi are able to cause allergic sensitization in humans and animals, while relatively few cause direct infection.

### Pathogenic effects

With very few exceptions, humans and the animal kingdom are incidental to the life history of fungi and pathogenic effects result from the accidental intrusion of fungal spores into the animal environment.

Generally, therefore, fungal diseases affect the skin and the lungs, organs in direct contact with the air in which spores are carried. Occasionally soft tissue infections may occur as a result of penetrating injuries that introduce soil-borne spores. The pulmonary syndromes associated with fungi in humans are asthma, hypersensitivity pneumonitis, saprophytic colonization and infection. Fungal spore asthma is discussed in Chapter 34 and hypersensitivity pneumonitis in Chapter 37. These syndromes may be pro-

voked by a large, and potentially limitless, number of fungal spores. In contrast, fungal infection and saprophytic colonization of the lungs occur with only a relatively small number of species, some of which (like *Candida*) are specialized to life within the animal organism and some of which (like *Aspergillus*) have developed mechanisms for survival in their natural habitat that coincidentally improve their chances of survival in animal lungs.

Thus, apart from hypersensitivity reactions, fungal diseases of human lungs are relatively uncommon and usually arise from the coincidence of an appropriate habitat, such as pulmonary inflammation or cavitation or reduced host immunity, and an organism with defence mechanisms appropriate to its survival in that environment. These matters are discussed further under the individual diseases.

### Sources of fungi

When a patient is shown to have fungal lung disease, the physician often wonders where the organism came from. The answer is almost invariably that it was inhaled from the ambient air. The air is full of fungal spores, liberated from organisms growing on dead or living vegetable matter [3]. Most of these spores are small and of appropriate size and shape to be respirable. In the summer in the UK, *Cladosporium*, plant rust and smut and *Fusarium* spores may be found in their tens of thousands in every cubic metre of air, while *Penicillium* and *Aspergillus* spores occur (in smaller numbers) predominantly in the autumn and winter months [4,5]. The numbers and species of spores differ in different climates, weather conditions and local vegetation. Many spores, such as those of *Coccidioides* or *Histoplasma* in the USA, may be found in soil and become liberated into the air when the soil is disturbed [6,7]. Huge numbers of spores have been observed to be released into the air in the meteorological conditions immediately prior to a thunderstorm [8], and may have some relevance to epidemics of asthma that occur in such circumstances. *Aspergillus* may be liberated from compost heaps [9] and when earth is disturbed by construction operations. Many species of fungal spore form an allergenic cloud round farmers at harvest time as the plant pathogens and saprophytes are disturbed [10]. Growth of fungus indoors may cause problems for asthmatics, and occasional outbreaks of fungal disease may result from, for example, careless removal of air filters in operating theatres or from fungal growth in air conditioners [11,12].

## Actinomycosis

### Aetiology

Actinomycosis may be caused by any one of the normal

mouth commensals, *Actinomyces israelii* (the most common), *A. naeslundii*, *A. viscosus*, *A. odontolyticus* (an important agent of dental plaque), *A. meyeri*, *Actinobacillus actinomycetes* and *Arachnia propionica*. There are no important differences in terms of the resultant clinical picture or response to therapy between these organisms. Infection has been reported from all over the world; malnutrition, immunosuppression and alcohol abuse may be predisposing factors but the primary cause of infection appears to be poor dental hygiene, oral trauma and aspiration of infected material into the lungs. All actinomycotic infection is in fact polymicrobial, the actinomycetes acting synergistically with anaerobes, particularly *Actinobacillus* and *Bacteroides* spp. This means that eradication of the main pathogen may not always result in complete resolution of the clinical condition.

### Clinical features

The most frequent manifestation of infection is a cervicofacial abscess [13–16]. Sometimes this can extend downwards directly into trachea or lung. Actinomycosis characteristically transgresses tissue planes and infection of the lung results in necrotic abscesses that invade adjacent structures, such as chest wall, mediastinum or pericardium [17,18]. In earlier times the patient often presented with abscesses pointing on the chest wall, but this is now very unusual in developed societies [19]. More frequently the patient presents with cough, purulent sputum and, occasionally, haemoptysis. Systemic symptoms of fever and weight loss are often not very prominent until the disease is well advanced. Metastatic spread to subcutaneous tissues, brain and other organs may occur in severe disease [20].

The diagnosis may be difficult and is often not suspected until the organism is demonstrated microbiologically [21]. Symptoms are non-specific and the radiograph may present any of a wide variety of changes; diffuse consolidation, fibrosis, cavitation and empyema all occur, and may be bilateral or unilateral. As the lesion may mimic bronchial carcinoma, resection is sometimes carried out before the diagnosis is made, suggesting that needle biopsy of such lesions might have prevented this intervention [22]. Associated periostitis of ribs or destruction of bone may be seen. The patient has often been treated with antibiotics, which makes the organism difficult to culture. Indeed, culture of actinomycetes from sputum may be of no relevance to coincident pulmonary disease in view of their normal presence in the mouth. However, the presence of chest wall or metastatic abscesses is a strong pointer to the diagnosis, which may be confirmed by microscopy of pus or biopsy material [23]. Specific stains for the various species may be used, but there are no serological tests of proven value.

The most characteristic feature of actinomycotic

infection, and one that allows the diagnosis to be made from examination of the pus, is the presence of 'sulphur granules'. These are yellow or white flecks, hard to the touch and about 2 mm in diameter, consisting of masses of hyphae cemented by a polysaccharide–protein complex and calcium phosphate [24]. Under the microscope they appear light brown, with a granular centre and radiating bands with eosinophilic clubs at the periphery (Fig. 21.1). They may sometimes be found in sputum if it is fixed directly in formalin rather than smeared for cytology.

The differential diagnosis is from other chronic lung infections (and tuberculosis may be very closely mimicked), other causes of empyema, and carcinoma. With modern techniques of investigation, such as transbronchial and needle aspiration, the diagnosis should be missed less frequently than in the past. In view of the difficulties in culturing the organism, the importance of its histological recognition in pus, sputum or tissue specimens cannot be overstressed.

### Management

All species of *Actinomyces* and *Arachnia* are sensitive to penicillin, and as soon as the diagnosis is made treatment should be started with 10–12 megaunits (6–7 g) daily intravenously [25]. Smaller doses orally may sometimes be adequate but have not always been effective in reported cases. If the patient is allergic to penicillin, tetracyclines, erythromycin, clindamycin, lincomycin and parenteral cephalosporins may be used and all have been shown to be active *in vitro* [26]. In chronic lung infection it is advisable to continue high-dose penicillin for 4–6 weeks followed by oral penicillin in a lower dose for up to 6 months. The presence of mixed infection with anaerobes should be

anticipated and appropriate antibiotics used. *Actinobacillus actinomycetem comitans*, the most frequent of these, is usually resistant to penicillin and requires treatment with a third-generation cephalosporin [27]. Abscesses, and particularly empyema, need to be drained and, in the absence of a satisfactory response to antibiotics, lung resection may be necessary. However, in view of the difficulties in a chronic, fibrosing infection, including the complication of bronchopleural fistula, this should be postponed until after a lengthy trial of medical treatment.

## Nocardiosis

### Aetiology

The family Nocardaceae consists of a number of species of Gram-positive, branching, filamentous aerobic bacteria that do not produce spores. They live on decaying organic matter in soil and are not natural inhabitants of humans, either as commensals or parasites. Nevertheless, fragments may become airborne and the primary route of infection in humans is via the respiratory tract. The usual organism found in human disease is *Nocardia asteroides*, but *N. brasiliensis*, *N. farcinica* and *N. transvalensis* have also been described as pathogens [28–30]. Infections occur predominantly in debilitated or immunosuppressed patients; alcohol abuse, chronic disease and corticosteroid therapy are frequent predisposing factors [31]. The most common causes of infection identified in a recent survey were immunosuppressives used to prevent rejection of transplants and for treating chronic pulmonary fibrosis, tumours and blood disorders, and immunosuppression as a consequence of human immunodeficiency virus (HIV) infection [32].

**Fig. 21.1** Photomicrograph of the edge of an actinomycotic 'sulphur granule' obtained from pus from a chest wall abscess. Note the strands of filamentous organisms. (Courtesy of Mr Michael Croughan.)

### Clinical features

Infection with *Nocardia* spp. cannot be distinguished clinically from other chronic pulmonary infections [25,31,33–35]. Non-specific symptoms of cough, loss of weight and appetite, purulent sputum and malaise are usual. The radiograph shows a wide range of abnormalities, including patchy opacities, streaky fibrotic-looking shadows, and diffuse infiltration; however, cavitation (single or multiple) is a frequent feature [36]. This infection, as well as that by *Aspergillus* spp., should be suspected when radiographic pulmonary nodules develop following transplantation [37]. Spread of infection by direct extension to pleura or mediastinum may occur [38], although chest wall fistulae are an unusual feature. Metastatic spread can occur to any part of the body, and brain abscess occurs in about one-third of all patients with disseminated disease.

The clinical course is of progressive deterioration and widespread dissemination in the absence of appropriate treatment. However, acute self-limiting pneumonic forms of the disease may occur. Other opportunistic infections may complicate the picture. The differential diagnosis includes tuberculosis, other mycobacterial infections, actinomycosis and fungal infections, especially aspergillosis. Diagnosis is made by demonstration of the organism in pus or histological material by Gram stain [39]; as stated previously, culture may be difficult and take several weeks. The absence of sulphur granules tips the diagnostic scales heavily in favour of nocardiosis rather than actinomycosis, although atypical granules may occasionally be seen. Serological tests are not generally considered to be of much value in making the diagnosis, but may be useful in following response to treatment.

### Management

The generally recommended treatment is with a sulphonamide such as sulfadiazine (sulphadiazine) (up to 9 g daily in ill patients) or trimethoprim–sulfamethoxazole (sulphamethoxazole) [25,32,33]. The treatment should be continued for several months, as metastatic abscesses may occur even after several weeks of treatment. Unfortunately, sulphonamides are not always effective and when this is the case, or when the patient is allergic to them, alternative therapy must be found. *In vitro* tests are not always a reliable guide to *in vivo* response, but the results should probably be taken into account in planning therapy. In various reports, minocycline, erythromycin, tobramycin, cycloserine, imipenem and amikacin have been shown to be effective. There is a case for combining two or more of these drugs in seriously ill patients. The importance of draining abscesses should be borne in mind when treating such patients.

### Diseases caused by fungi

As stated above, fungi can exert pathogenic effects by allergic sensitization (causing asthma or allergic alveolitis), saprophytic colonization of the lung, or invasion and tissue damage. All airborne fungal spores have at least the potential to cause asthma; many of appropriate size, if inhaled in high dosages, may cause alveolitis. Saprophytic colonization of lung cavities may occur if spores can gain access to, and germinate in, the cavity. The specific factors that allow this are presence in the air in adequate numbers, sufficiently small size to be respirable (<10 µm in aerodynamic diameter) and ability to germinate in the presence of the lung's defences and at 37°C. These factors are discussed further in the section on *Aspergillus*. Pathogenicity in the sense of causing lung and systemic infection is a characteristic of relatively few fungi that have developed specific mechanisms for overcoming the body's defences, but a larger number of organisms have the potential to cause infection if the immune system is impaired. However, relatively few of these opportunistic pathogens cause disease other than very occasionally. In this section, the diseases are considered under the various fungal genera, the normally pathogenic organisms being discussed first and then the opportunistic ones.

### *Blastomyces*

#### Aetiology

North American blastomycosis is caused by *Blastomyces dermatitidis*, a dimorphic fungus that exists in both yeast-like and mycelial forms. The proper name, associated with its perfect or sexual form, is *Ajellomyces dermatitidis*. Little is known about the ecology of the organism which, though generally believed to be a soil inhabitant, nevertheless does not apparently survive well in soil [40,41]. It is introduced into humans by inhalation of either spores or the yeast form [42]. Small outbreaks of infection have been reported, suggesting point sources of heavy exposure, although most cases are sporadic and reported relatively uncommonly even in endemic areas [43,44]. The disease does not seem to be a particular hazard of the immunosuppressed, although episodes of infection in patients with neoplasms and those on corticosteroids have been described [45], and it has been reported as a late and serious disseminated infection in patients with AIDS [46]. It seems likely that exposure to a heavy infecting dose is more important than impaired defences in the aetiology of blastomycosis. This concept is supported by the occasional occurrence of laboratory infections [47]; clearly care has to be exercised in handling the organism. However, person-to-person infections do not seem to occur.

Study of the distribution of the organism and its

infectivity has been hampered by the lack of a sufficiently sensitive skin or serological test. The distribution of cases of disease is largely confined to areas surrounding the major waterways of North America, the Ohio and Mississippi basins, the southern Great Lakes and the St Lawrence seaway [43,48]. However, cases have also been described in people from many parts of Africa and from Saudi Arabia [49,50].

Once inhaled, the organism exerts a strong chemotactic effect towards polymorphonuclear leucocytes, causing a mixed leucocytic and granulomatous reaction. Although the organism appears to become associated with phagocytic cells, it is resistant to killing, and may be seen to multiply within macrophages and giant cells [50,51]. Nevertheless, human bronchoalveolar macrophages do have some fungistatic and fungicidal activity against the organism [52].

### Clinical features

Blastomycosis may present as an acute or chronic form [53–55]. The acute disease is clinically indistinguishable from other pneumonic illnesses, with general malaise, fever, cough and pleurisy. Sputum, if produced, is purulent. The radiograph shows lobar or segmental consolidation, which may be confluent or patchy; effusion is uncommon [56]. The acute illness may remit spontaneously over a few weeks [57], but more commonly progresses to an indolent form of the disease. Sometimes the progression is rapid, with diffuse intrabronchial spread leading to the adult respiratory distress syndrome and death [58,59].

Chronic blastomycosis may follow the acute disease or may occur without an obvious clinically acute episode. Irregular streaky and nodular radiographic densities on the chest radiograph, together with persistent malaise, weight loss and cough, mimic tuberculosis [56–60]. Cavitation occurs frequently and miliary mottling occasionally, making the distinction even more difficult. Alternatively, the disease may present as a solid mass in one lung, simulating bronchial carcinoma. Chronic fibrosing mediastinitis has been described leading to superior vena caval obstruction, though this is more commonly caused by histoplasmosis [61]. Chronic blastomycosis is very frequently associated with metastatic disease in organs other than the lung. Skin and subcutaneous tissues (from which manifestations the organism acquired its specific name), bone, prostate and epididymis are frequently the sites of chronic abscesses, and other organs may be affected rarely.

### Diagnosis

The diagnosis should be borne in mind if a patient lives in or has recently visited an endemic area, especially North

America. Serological methods now provide a specific test, though false negatives occur in up to 25% of patients. An enzyme immunoassay for the A antigen of *B. dermatitidis* seems to be the most sensitive test so far available [62,63]. Nevertheless diagnosis depends on demonstration of the organism in sputum, pus, lavage fluid, needle aspirate or tissue sections. It is a characteristic yeast-like organism, about 8–15 µm in diameter, with a highly refractile cell wall and multiple nuclei. It can be seen in unstained sputum preparations, preferably treated with potassium hydroxide to digest other cellular debris. In histological sections it may be stained by Gomori's method or by periodic acid–Schiff stain. It may be cultured on enriched media at 30°C; the mycelial form may grow and need to be subcultured to produce the yeast form for identification.

### Treatment

In view of the high risk of progression and death in blastomycosis, it is advisable to treat all patients in whom the diagnosis is made. Amphotericin remains the treatment of choice and should be given in a total dose of at least 2 g over 10–12 weeks [64,65]. Up to 50 mg daily may be given in seriously ill patients; in less sick individuals the same dose may be given on alternate days. The drug should not be withheld in pregnant patients in view of the seriousness of the disease and the absence of reports of fetal toxicity [66]. Ketoconazole has also been used to good effect in blastomycosis, in a dose of 400 mg daily for up to 6 months. However, not only is it a rather toxic drug with teratogenic effects but failures have occurred in seriously ill patients, so it should probably be reserved for people with relatively mild infections [67,68]. Fluconazole has also proved moderately effective in non-life-threatening infections, given at up to 400 mg daily for 6 months or more [69]. A new triazole has proved effective in murine blastomycosis and is likely to be available for trial in humans in the near future [70].

## Coccidioides

### Aetiology

Coccidioidomycosis (known familiarly and understandably by physicians in the south-western USA as 'coxy') is caused by *Coccidioides immitis*, a dimorphic fungus known only in its asexual or imperfect form. It grows as a hypha in hot, dry soil and its known habitat is confined to desert and semi-desert regions of the south-western USA, Mexico and South America. It has been noted that it shares this habitat with the creosote bush and that its presence in soil is most profuse around rodent burrows [71,72]. The hyphae become septate and reproduce by segments (or arthrospores) breaking off. These can germinate again in suitable soil or, if inhaled by an animal, can reproduce by

the production of endospores within the original spore capsule, now called a spherule. This ruptures to liberate several hundred spores which, aside from causing an inflammatory response in the host, return to the soil via sputum or other infected body fluids or in animal carcasses; the cycle is then completed by germination in the hyphal form.

The organism excites an immune response in the host, with influx initially of macrophages and neutrophils and later of mononuclear cells. The end-result is a granulomatous lesion pathologically and a T lymphocyte-mediated immune response. There is some evidence that the infection itself may cause impairment of T-lymphocyte function [73,74].

The disease coccidioidomycosis is confined to those who live in or have recently visited endemic areas, or laboratory workers exposed to the hyphal form of *C. immitis*. In particular, outbreaks have been described following dust storms and among archaeology students digging Indian sites in southern California, Arizona and New Mexico [6,75,76]. Epidemiological studies have shown infection to occur in a high proportion of people living in these areas; although subclinical infection is common, clinical illness is also frequent and, because of its debilitating nature, of considerable economic importance [77,78]. There is evidence of an increase in the numbers of people infected in endemic areas, to the extent that the disease is reaching epidemic proportions [79,80]. The infectivity of the organism is illustrated by the observation that 8 of 27 Marine Corps reservists training in the Californian desert contracted infection, seven showing symptoms [81]. Not unexpectedly, in endemic areas coccidioidomycosis has become an important and highly fatal pathogen in patients with HIV infection [82].

### Clinical features

Up to two-thirds of those infected exhibit either very mild or no symptoms [83–86]. Most of those with significant symptoms have an acute illness, with fatigue, cough, fever, malaise and chest pain. Systemic manifestations of a hypersensitivity reaction are common; arthralgia, erythema nodosum or multiforme and phlyctenular conjunctivitis may occur. The radiograph may show bilateral hilar node enlargement, although pneumonic changes are usually unimpressive [87]. However, lobar, patchy or bronchopneumonic consolidation may occur and severe confluent pneumonitis may precipitate acute respiratory failure [76,88]. Miliary dissemination may also occur, with involvement of bone, meninges and skin in particular. This potentially fatal progressive syndrome is more common in the immunosuppressed, dark-skinned races and women in the later stages of pregnancy [88,89]. It is associated with failure to produce a delayed skin hypersensitivity reaction, which may be due to antigenic over-

load in those subjects who are not immunosuppressed [90,91].

Most patients improve gradually without treatment over a few weeks, though fatigue and general debility may last for some months. A few, less than 1%, progress to the chronic disease, in which persistent lung infection may cause chronic pulmonary fibrosis, cavitation or solitary nodules [92–94]. Cavities may resolve spontaneously but more frequently persist and enlarge. This chronic syndrome may be associated with symptoms of malaise and is usually the cause of productive cough. It may lead eventually to respiratory failure. Chronic pulmonary coccidioidomycosis occurs particularly in patients with disorders of cell-mediated immunity.

### Diagnosis

Coccidioidomycosis should be suspected in anyone with an acute systemic illness with pulmonary features who has recently visited an endemic area. Reactivation of disease may also be suspected in someone treated with immunosuppressant drugs or with HIV infection who previously lived in such an area. Diagnosis is made by demonstrating the characteristic spherule in sputum or pus aspirated from a lesion. If sputum studies are negative, fiberoptic bronchoscopy with washing and brushing are helpful diagnostic tests [95]. Any endobronchial inflammatory lesion should be biopsied; transbronchial biopsy should be carried out if a radiographic lesion is present and accessible. Fine-needle biopsy is used increasingly, and diagnosis depends on demonstration of the spherule or, less commonly, culture of the organism [96]. Finally, in some cases of unexplained pulmonary shadows or nodules, thoracotomy may be necessary.

The spherule can be stained with Gomori's or Papanicolaou's stains, and may also be demonstrated on sections stained with haematoxylin and eosin. The organism can be cultured on mycological media, but this should only be attempted in specialized laboratories because of the hazard of infection by arthrospores [97]. Newer molecular techniques have resulted in production of nucleic acid probes to coccidioidal RNA, and commercially available probes hold hope of identifying the organism in culture within a few days [98]. IgM precipitating antibodies to coccidioidin antigen from the mycelial phase may be demonstrated in a high proportion of patients within 3 weeks of onset of disease, while IgG complement-fixing antibodies occur later but may persist for about 6 months; one or other of these antibodies can be demonstrated in 90% of patients [99]. Skin tests with antigens derived from mycelial phase (coccidioidin) and spherule phase (spherulin) are available, and delayed reactions can be shown in most infected patients quite early in the illness [100]. However, they are not of much use diagnostically unless the patient's reaction was known prior to the

illness, and these tests have their main application in epidemiology and control programmes.

### Treatment

Most patients require no treatment other than that needed for amelioration of acute symptoms. However, if symptoms persist for over 6 weeks, progressive or disseminated disease occurs or very high titres of IgG antibody are found, it is generally recommended that antifungal agents should be used [64]. Amphotericin, in doses as for blastomycosis, seems the most effective therapy [101,102], but ketoconazole has also been shown to be a useful alternative. While ketoconazole penetrates relatively poorly into the cerebrospinal fluid, in high (800 mg daily) doses it may be effective in meningeal disease [103]. In chronic cavitating pulmonary disease, resection of lesions may occasionally be necessary. Because of time lost from work and medical costs, the economic importance of coccidioidomycosis in endemic parts of the USA is such that a vaccine would be extremely useful. One that showed good protection against experimental disease in laboratory animals has to date shown no significant benefits in a human trial [104].

## Cryptococcus

### Aetiology

Cryptococcosis (previously called torulosis) is caused by the yeast form of the dimorphic basidiomycete *Filobasidiella* spp. [105]. The organism was originally thought to exist only as a yeast and the name of this imperfect form, *Cryptococcus*, has been maintained in medical usage. Disease is normally caused by *Cryptococcus neoformans*, of which several different serotypes have been described [106]. The serotype *C. neoformans* var. *gattii*, found especially in Australia and Papua New Guinea, is associated particularly with infection of the immunocompetent, whereas the more widespread variety *neoformans* is increasingly associated with infection of the immunosuppressed [107,108]. Two other species, *C. laurentii* and *C. albidus*, have also been implicated in pulmonary disease [109,110]. The organism may be found in soil, although it is not known whether the yeast or the hyphal form is predominant. It is most readily found in bird, especially pigeon, droppings and in soil contaminated with such excreta [111]. The variety *gattii* has been associated with eucalyptus trees, although little is known of its natural habitat. The perfect form produces spores sexually that may become airborne and are of appropriate size to be inhaled to alveolar level. Likewise, the yeast form is only about 5 µm in diameter and therefore potentially respirable; the evidence now strongly suggests that the primary route of infection in pulmonary, neurological and

disseminated cryptococcosis in humans and in experimental animals is via the respiratory tract [112].

The organism occurs widely throughout tropical and temperate zones and is probably inhaled by many people and animals without causing disease. There is clear evidence of different degrees of resistance to infection by different species of animals. High rates of skin sensitization to *Cryptococcus* have been shown in groups of healthy pigeon-breeders and exposed laboratory workers [113,114]. When disease does occur, it appears to be sporadic and there is no evidence of transmission from humans or other animals to humans. Although the disease is recognized increasingly in AIDS patients and in those on corticosteroids or immunosuppressant drugs [115–117], pulmonary infection has been reported quite frequently in otherwise healthy people. In those parts of the world where *C. neoformans* var. *gattii* occurs, such as Australia and Papua New Guinea, pulmonary infection often in association with meningitis is not uncommon in such previously well people.

Infection with *Cryptococcus* is not associated with a brisk inflammatory response. Instead, there is evidence of profuse growth of organisms with a predominantly macrophage and giant cell reaction; some plasma cells and lymphocytes may be present but well-formed granulomas are not common. In these infected tissues, *Cryptococcus* is seen to be surrounded by a thick capsule. This is composed of polysaccharide and may be of value to the organism by preventing its recognition by host defences and by enlarging it sufficiently to be too big for ingestion by macrophages. The organism appears to excite a cell-mediated immune response, although humoral antibodies are also produced [118,119]. When severe infection occurs, the most dangerous lesions are found in the brain and meninges. Presumably the organism is carried there by the bloodstream and finds appropriate conditions for growth; it has been shown that cerebrospinal fluid is a good culture medium and that inflammatory responses to *Cryptococcus* are delayed or absent in the brain [120,121].

### Clinical features

Pulmonary disease due to *Cryptococcus* is rare and in many cases appears to have been asymptomatic and self-limiting [111,122–125]. However, the lungs are important as the site of entry of the organism when it causes neurological or disseminated disease; very occasionally, pulmonary manifestations are the dominant or only clinical feature. Patients with pulmonary cryptococcosis may be free of symptoms or have non-specific complaints. The radiological features vary, but solid lesions resembling pulmonary or mediastinal tumours or abscesses are most frequent. Lobar collapse due to intrabronchial mass and Pancoast's syndrome are two presentations mimicking carcinoma that have been described [126,127]. The find-

ings may also mimic tuberculosis, pneumonia or metastases and the diagnosis can only be made by demonstrating the organism.

In view of its rarity, pulmonary cryptococcosis is usually not suspected before the lesion has been removed. However, it should be borne in mind in the differential diagnosis of unusual radiological appearances in patients with immunosuppression due to drugs, AIDS or malignant disease. In such patients, meningeal and encephalitic features occur commonly, and the insidious onset of headache, behavioural changes and cranial nerve lesions should alert the physician to this possibility [117,128].

### Diagnosis

The organism may be cultured on Sabouraud medium from sputum within 48 h, but this is not necessarily diagnostic unless it can be found repeatedly [123]. Antibodies to *Cryptococcus* may be helpful, and a latex agglutination test has been developed that is specific (in the absence of rheumatoid disease and if IgM antibody has been removed) and reasonably sensitive [129]. The presence of the organism in cerebrospinal fluid can be regarded as diagnostic of neural involvement. Generally, however, diagnosis depends on direct demonstration of the organism in biopsied or aspirated tissue (Fig. 21.2), when the doubly refractile cell wall, the presence of budding and the clear capsule (as shown by Indian ink or nigrosin preparations) are characteristic. Bronchoalveolar lavage fluid or needle aspirates guided by ultrasound if necessary are useful methods of making the diagnosis in cases of diffuse lung infiltration and nodular changes on the radiograph [116,130].

### Treatment

While there may be a case for withholding treatment from patients with minimal pulmonary disease that has been diagnosed by removal of the lesion, in most cases it is advisable to treat the patient with antifungal drugs once the diagnosis has been made in order to prevent both progressive pulmonary disease and involvement of the brain and meninges. Standard doses of amphotericin and flucytosine in combination over 6 weeks are regarded as the best therapy [131].

### *Paracoccidioides*

#### Aetiology

Paracoccidioidomycosis, also known confusingly as South American blastomycosis, is caused by the dimorphic fungus *Paracoccidioides brasiliensis* [132]. The organism probably lives in soil and has been found in the faeces of bats and other animals, although little is known of its natural history. The mycelial phase produces spores of respirable size when grown on culture media with reduced carbohydrate content at 25°C, while at higher temperatures the organism grows as a yeast form and reproduces by budding, usually in a characteristic daisy-wheel pattern. The yeast phase varies considerably in size, from 4 to 40 µm.

Paracoccidioidomycosis is confined to patients from Central and South America, particularly in areas of tropical and subtropical forestation. Most cases have been reported from Brazil, although occasionally the disease is diagnosed in patients from South America who have

**Fig. 21.2** Alveoli of patient with AIDS showing organisms of *Cryptococcus* (arrowed). There is also granular material of *Pneumocystis* infection and one of the cryptococcal organisms is budding (arrowhead) (alcian blue  $\times 410$ ). (Courtesy of Dr Nick Francis.)

migrated to other countries, often after a long latent period. Skin-test surveys have suggested a higher rate of infection than might be anticipated from the relatively small number of clinical case reports. Overt disease seems to occur predominantly in adult males, and especially those engaged in agriculture. It seems very likely that infection occurs through inhalation of spores, and primary complexes have been shown in lungs. However, transmission between patients has not been described.

### Clinical features

Two syndromes, acute and chronic, have been described [132–134]. In the acute condition, which mainly affects young people, there is involvement of lymph nodes, liver and spleen with a systemic illness, the lungs being involved by bronchopneumonic consolidation occasionally [135]. It is a serious and often fatal condition, and the most important cause of adrenal insufficiency in endemic areas. The chronic form affects older males primarily and is often severe, with progressive pneumonic consolidation causing cough, chest pain and breathlessness. Fever, weight loss and anorexia are common and the disease runs a slowly progressive course, often disseminating to other organs; mucosal and facial ulcers and lymphadenopathy are common accompaniments. The pulmonary manifestations are very varied, ranging from calcified granulomas to diffuse infiltration. Dense consolidation, cavitation and tumour-like masses may occur and may lead to fibrosis and acute or chronic respiratory failure. Occasional reports have documented its occurrence in individuals on immunosuppressant drugs, when presumably latent infection is reactivated [136].

### Diagnosis

The condition should be suspected in people from Latin America with appropriate symptoms. In many cases the organism can be demonstrated in sputum cleared with potassium hydroxide. If this is unsuccessful, bronchial brushings and washings and transbronchial biopsies should give the answer. The organism can be cultured on Sabouraud medium. An immunodiffusion test for precipitating antibodies is available, though a positive test may not necessarily mean active infection.

### Treatment

*P. brasiliensis* is unusual among pathogenic fungi in being sensitive to sulphonamides, although treatment with these drugs needs to be continued in high dosage (e.g. sulfadiazine 4–6 g daily in adults) for several months and then in lower dosage for 3–5 years. In severe cases, amphotericin is used in addition. These measures may be insufficient, and reports of treatment with ketoconazole and

itraconazole have been encouraging [136–138]. This treatment should also be continued for at least 1 year, depending on therapeutic response, as the disease has a tendency to relapse and up to 25% of patients die of it. When treatment is successful, healing occurs by fibrosis.

## Histoplasma

### Aetiology

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. Its misleading name stems from the fact that it was originally thought to be a plasmodium and because in fixed tissue it shrinks and looks as if it is surrounded by a capsule. In fact it is the imperfect yeast form of the mycelial fungus *Emmonsia capsulata*, an organism that lives in soil and prefers habitats heavily contaminated by bat or bird faeces [139]. Although it has been reported from many tropical and subtropical parts of the world, pulmonary and systemic histoplasmosis can only be considered to be endemic to North America, mainly in the states bordering the Mississippi, Missouri and Ohio rivers [140]. Only very occasionally has histoplasmosis been reported from the UK and Ireland, usually in patients who had spent parts of their lives in India, the Far East or Africa [141,142]. An African form of histoplasmosis caused by the same organism occurs, in which skin and bone lesions predominate and lung infection has been rare.

The fungus in its mycelial phase produces spores of two sizes: the larger, about 8–10 µm, have multiple fine projections from their surfaces, while the smaller, 2–6 µm, tend to be smooth. Both are potentially respirable and inhalation is the mechanism whereby humans are infected. On inhalation the spore germinates at body temperature into the yeast form, which attracts and is phagocytosed by macrophages. However, it is resistant to killing and reproduces within the macrophage by budding until the cell may be full of organisms [143,144]. Animal studies have shown that, in the unsensitized, within about 2 weeks the infection excites a strong local vasculitic response, with necrosis of lung and lymph nodes. The initial response in mice has been shown to be a neutrophil alveolitis, followed by an influx of lymphocytes at about the second week after challenge. Subsequently a granulomatous reaction occurs and this seems effective in killing the organism and leading to resolution of the pathological changes [145]. At this stage the macrophages' ability to kill the ingested *Histoplasma* is enhanced and healing occurs by fibrosis. In previously sensitized animals, the process is repeated but with much less initial proliferation of the organism and with the necrotic and healing process starting within 48 h. The accelerated reaction is due to an immune response mediated by sensitized lymphocytes [146].

Epidemiological surveys have shown evidence of high

levels of skin sensitivity to *Histoplasma* in endemic areas [140], and the finding of healed, calcified pulmonary foci in well people in such areas is commonplace [147]. Infection sufficient to cause clinical disease is probably related to the exposure dose of spores and many outbreaks have been described as a consequence of heavy exposure to point sources, for example clearing out chicken roosts or pigeon lofts, digging contaminated soil and exploring bat-infested caves and belfries [148–150]. Such exposures result in acute disease. Chronic pulmonary disease seems more related to the presence of pre-existing lung disease, such as emphysema or bronchiectasis, where the organism can gain a foothold [151], while disseminated disease largely afflicts the immunosuppressed and infants [152].

### Clinical features

Acute histoplasmosis may range from a mild, influenza-like illness with no pulmonary signs, through an acute episode with cough, chest pain and hilar adenopathy on

chest radiography, to a severe illness with fever, dyspnoea, cough and extensive radiographic changes [148,153]. There may be a history of recent exposure in an endemic area. While the symptoms of acute disease are non-specific, the radiological changes in severe cases may be characteristic, with bilateral, multiple fluffy or coarsely nodular infiltrates in association with hilar node enlargement (Fig. 21.3). In such patients there may be dissemination of disease, in that the organism can sometimes be cultured from bone marrow, but obvious clinical involvement of tissues other than lung is rare. Pleural effusion occurs uncommonly and is usually small [148].

In most cases, acute histoplasmosis is a self-limiting illness, the symptoms gradually resolving over a period of a week or two while the radiographic shadows consolidate into small nodules that in time calcify (Fig. 21.4). Rarely the disease progresses to respiratory failure and death, or symptoms occur from local effects of necrotic lymph nodes; rupture into pericardium, compression of trachea, oesophagus or superior vena cava, and production of mediastinal infection and fibrosis have been

**Fig. 21.3** Bilateral diffuse nodular infiltrates in a patient with acute histoplasmosis. (Courtesy of Dr N.L. Lapp.)

**Fig. 21.4** Calcified nodules of healed histoplasmosis. (Courtesy of Dr N.L. Lapp.)

described. Solitary, slowly enlarging pulmonary nodules may occur and the diagnosis may often be suspected because of a calcified centre, sometimes with surrounding calcified laminae [154].

Disseminated histoplasmosis may follow pulmonary infection [152,155,156]. In infants and immunosuppressed adults, this may take an acute form with general malaise, fever, hepatosplenomegaly and generalized lymphadenopathy. Anaemia and leucopenia are common and some patients have radiographic evidence of a diffuse interstitial pneumonitis. This disease is fatal if not treated. However, subacute and chronic forms of disseminated histoplasmosis are also recognized, and these are the types most likely to be imported into the UK [141]. Weight loss, malaise and fever are common symptoms, chronic upper lobe pulmonary fibrosis may be present, and Addison's disease, skin or mucous membrane ulcers, intestinal ulcers, endocarditis or meningitis may occur. Such patients may develop this form of disseminated disease after starting immunosuppressant drugs or when they develop autoimmune disease or neoplasia.

Chronic pulmonary histoplasmosis occurs largely in patients with pre-existing lung disease [151]. The lesions are normally in the apical and posterior segments and appear as a combination of streaky and fluffy opacities, with a tendency to harden and contract. Cavitation may occur and the cavities may enlarge progressively. Differentiation from tuberculosis or atypical mycobacterial infections is difficult. Symptoms may be few or absent until the disease is well advanced, when respiratory failure may

supervene as a result of the combination of primary lung disease and secondary infection with *Histoplasma*.

In Africa a variant, *H. capsulatum* var. *duboisii*, has been described as a cause of a chronic form of histoplasmosis [157]. The lungs have rarely been involved, lesions predominating in skin, bones and reticuloendothelial system; however, the epidemic of AIDS is probably changing this and lung and systemic infection is now being reported [158].

### Diagnosis

In endemic areas, acute histoplasmosis may be diagnosed on clinical grounds with the support of a positive complement fixation test; titres greater than 1/32 or a fourfold rise are strong evidence of infection if the clinical features are consistent with the diagnosis [159]. Other serological tests that may be of help (but which are of greater value in epidemiological studies) are radioimmunoassays for specific *Histoplasma* IgM and IgG antibodies [160,161]. In disseminated disease the diagnosis depends on demonstration of viable organism in macrophages or giant cells, in either tissue biopsies, blood, bone marrow or urine [156]. Blood cultures are usually positive in acute disease whereas liver and marrow biopsies are better in the subacute and chronic forms. When the lung is involved, either in disseminated disease or in chronic pulmonary histoplasmosis, brushings, washings and transbronchial biopsies may be helpful if sputum cultures are negative (Fig. 21.5). A radioimmunoassay for capsular antigen in blood, urine or

(Courtesy of Dr Nick Francis.)

bronchoalveolar lavage fluid is available and has proved particularly useful in the detection of disseminated disease [162–164].

### Treatment

Most patients with acute histoplasmosis will settle without treatment [64,165–167]. The few that show progressive disease require amphotericin. Disseminated disease should also be treated with amphotericin 0.6 mg/kg daily up to a total of about 3 g. Less acute cases of disseminated disease and chronic pulmonary histoplasmosis may alternatively be treated with ketoconazole 400 mg daily for up to 1 year, with cure rates of over 80%. Fluconazole and itraconazole have both been used successfully as oral treatment in less severe infections, in which they may be used as initial treatment, and as continuation therapy after initial control with amphotericin [168–170].

### Sporothrix

#### Aetiology

Sporotrichosis is caused by the dimorphic fungus *Sporothrix schenckii*, which may be found in soil and living or dead plants [171]. The organism may be inhaled either as spores or in the yeast form, both being of respirable size. Usually, however, it enters the body via abrasions and causes chronic granulomatous skin lesions [172]. Cat scratches and handling of sphagnum moss are important causes in endemic areas. Disease occurs only sporadically, most commonly in Mexico and Brazil, but also very occasionally in many other countries including the USA and Japan. Epidemics have been described in South African gold miners exposed to the organism in rotten timber [171]. Cases have not yet been reported in the UK.

#### Clinical features

Pulmonary sporotrichosis is rare and has most usually presented with localized shadowing in an upper lobe that may progress to cavitation [173–175]. It is usually thought to be tuberculosis or another mycobacterial infection, thus delaying the diagnosis which is best made by excision of the lesion and culture of the organism. Apart from skin lesions, other organs occasionally involved include bones and joints, conjunctiva and, very rarely, the nervous system.

#### Treatment

Pulmonary sporotrichosis is often treated by excision prior to the diagnosis being made [176]. Amphotericin is effective but the newer and less toxic oral antifungal drug

itraconazole has been used successfully and will probably become established as first-line treatment in severe infections [177,178]. Skin lesions may respond to oral potassium iodide.

### Aspergillus

#### The organism

The genus *Aspergillus* includes several species known to have pathogenic effects on humans. *A. fumigatus* is the one most frequently associated with disease, but *A. niger*, *A. flavus*, *A. terreus*, *A. clavatus*, *A. glaucus* and *A. nidulans* among others have been described as causes of pulmonary or disseminated disease [179–182]. Air sampling has shown that, of these, only *A. fumigatus* and *A. niger* occur with any frequency in the ambient atmosphere in the UK [183]; they are present most profusely in the winter and this is explained by their need for dead organic matter as a substrate [9]. Thus they thrive on fallen leaves and in compost heaps, and may be found widely throughout vegetated parts of the world. As would be expected, different species of *Aspergillus* may be the dominant organisms in different climates; thus *A. terreus* has been shown to be more prevalent than *A. fumigatus* in Texas [184].

*Aspergillus* is one of the large group of imperfect fungi having no known sexual stage. It has a hyphal form and reproduces by producing spores generally less than 3 µm in diameter and which are dispersed by wind. In general, *Aspergillus* spp. (particularly *A. fumigatus*) have temperature optima for growth at about 37°C. These two characteristics fit them well for a pathogenic role in warm-blooded animals, though it seems unlikely that animals are anything other than an unnecessary diversion from their normal life cycle. The organisms grow readily on standard mycological media at 37°C and may be recognized by their septate, branching hyphae and the swollen conidiophores. It is from its resemblance to the aspergillum of the Catholic ritual that the organism takes its name (Fig. 21.6).

#### Diseases associated with *Aspergillus*

*Aspergillus* spp. are unique among the fungi in the number of different pathological reactions with which they may be associated. Nevertheless, they are opportunistic organisms with respect to infectivity. In common with many other fungi that produce spores they may be allergenic, provoking exacerbations of asthma when natural air counts rise, as in the winter, or in proximity to compost heaps. Furthermore certain asthmatic patients may develop a hypersensitivity reaction, allergic bronchopulmonary aspergillosis [185], while non-asthmatic individuals exposed to very high doses of spores may develop typical allergic alveolitis [186]. Spores may also land in old

**Fig. 21.6** Scanning electron micrograph of conidiophore of *Aspergillus fumigatus*.

pulmonary cavities or cysts and germinate there, causing aspergilloma [187]. Finally, the spore may take advantage of the presence of local lung disease (such as infarct, tumour or pneumonia) or of generalized impairment of defences (such as leucopenia, leucocyte dysfunction or immunosuppressant therapy) either to become locally invasive or to cause disseminated disease [188].

#### Factors associated with pathogenicity

*Aspergillus* illustrates particularly well the importance of the two factors involved in pathogenicity: the inherent properties of the organism and the defences of the individual host. Some animal species, such as penguins and other birds, have very little inherent resistance to the organism and thus it is an important cause of severe lung infection. Humans on large doses of corticosteroid and immunosuppressant drugs are in the same position. The atopic individual may develop asthma as a result of exposure to levels of spores that would otherwise have no pathogenic effect. Large doses of spores may have an antigenic effect through complement activation in otherwise normal people. Of course, patients with defective leucocytes, for example in leukaemia, lymphoma or chronic granulomatous disease, are at special risk of disseminated disease [188,189].

On the other hand, why should *Aspergillus*, of all the fungal spores in the air, have the potential to cause so much trouble to the animal kingdom, on which it does not depend for its natural survival? Its spore size and optimum temperature and oxygen requirements clearly mean that, probably by chance, it is ideally suited to survival within the airways [183]. However, in addition, it seems to have developed sophisticated defence mechanisms against macrophages and neutrophils. *In vivo* experiments in mice have shown that injected spores may be killed by both macrophages and neutrophils [190,191]. However, *A. fumigatus* is certainly resistant to phagocytosis by these cells from both rodents and humans [192,193] and, moreover, appears to produce a substance, as yet unidentified, that inhibits phagocytosis, macrophage migration and macrophage spreading [193–196]. It may be that it has evolved such a mechanism in order to protect itself from protozoa in soil, the natural predators of fungal spores [197–199].

#### Asthma and allergic bronchopulmonary aspergillosis

*Aspergillus* is one of many fungal spores that can provoke attacks of asthma. Several allergens have been described, one of which (*Asp*fI) appears to be present only in hyphae and is therefore only of relevance when the organism is

germinating in airways as in allergic aspergillosis [200], while another, gp55, is a glycopeptide of about 50kDa [201]. Allergenecity becomes of practical importance in three situations.

1 In atopic individuals and in children with cystic fibrosis [202], who may become sensitized and develop asthmatic symptoms and allergic aspergillosis.

2 When high levels of spores (or antigen derived from spores or hyphae) are present in the air in a workplace. This has been described in workers on farms, in sugar mills and in those producing citric acid by fermentation of molasses with *A. niger* [203,204]. In such circumstances, atopic individuals seem to be at greatest risk of developing sensitization and the organism is apparently a rather weak sensitizer [205].

3 When the immune responses of the individual are such as to provoke extrinsic allergic alveolitis. This condition may occur in workers exposed to mouldy hay or compost heaps [186], *A. fumigatus* being one of the organisms associated with attacks of farmers' lung. In these circumstances, the disease may present as a combination of asthma and alveolitis, with evidence of immediate and delayed skin sensitivity, and both airflow obstruction and reduction in lung volumes and transfer factor.

Allergic bronchopulmonary aspergillosis usually occurs in asthmatic individuals, although the first sign of the asthma may be an episode of aspergillosis. It may also occur occasionally in the absence of clinical evidence of asthma, in otherwise healthy people, although most of these prove to be atopic on skin testing [206]. Patients with cystic fibrosis are also at risk of developing bronchial colonization by *Aspergillus* and may show evidence of bronchopulmonary aspergillosis [207–209]. It is important to recognize that there is a spectrum of response to aspergillar antigen, from simple skin sensitization in atopic individuals, to sensitization with asthmatic symptoms, to asthma plus occasional episodes of aspergillosis, to persistent aspergillosis with progressive lung damage. The patient with allergic aspergillosis typically presents with an exacerbation of wheeze and cough, often associated with fever and malaise [210–212]. Such attacks occur more usually in autumn and winter than in summer [213]. The cough is unproductive at first but subsequently, especially after treatment with corticosteroids, may be associated with the production of viscous sputum containing plugs. Haemoptysis is not uncommon, though rarely more than minor. The radiograph shows features that distinguish the episode from a simple exacerbation of asthma: patchy infiltrates and band shadows, typically confined to one or two segments, are present. Occasionally segmental or lobar collapse may be a feature. Recurrent episodes are associated with similar shadows, sometimes in the same part of the lung and sometimes elsewhere [213,214] (Fig. 21.7). Bronchiectasis is often present in parts of the lung previously affected by inflammatory change.

This is sometimes confined to the proximal segmental bronchi, sparing the more peripheral, but this is far from always the case [213,215] (Fig. 21.8). The blood count typically shows eosinophilia, and immediate skin sensitivity to aspergillar antigen is present on prick testing. Intradermal tests, which are rarely necessary, often show delayed reactions of the Arthus type as well. Strong IgG precipitating antibodies are present in about 70% of patients and high levels of specific IgE are usual [216]. While cross-reactivity between different species of *Aspergillus* is frequent, it should be noted that in some patients negative tests for delayed hypersensitivity to *A. fumigatus* and other species may occur when the organism is *A. terreus* [217]. The sputum may show hyphae (Fig. 21.9) and the organism may sometimes be cultured from it; only the presence of hyphae can be regarded as confirmatory of the diagnosis, as fungi can commonly be cultured from anyone's sputum whenever the appropriate spores are available to be inhaled from the ambient air [183].

The sputum is typically viscous and contains plugs or casts of bronchi. Histologically these show, apart from hyphae, the stigmata of asthma, namely eosinophils and desquamated epithelial cells. These changes are a reflection of the pathological changes in the bronchi from which they came. The lung itself distal to the bronchial reaction shows an eosinophilic infiltration.

There is some confusion about the natural history of allergic aspergillosis, since many descriptions in the literature are of patients from the severe end of the spectrum who had been investigated in specialist centres. However, most episodes resolve rapidly without permanent lung damage on the administration of corticosteroids. Early treatment of acute episodes with corticosteroids therefore normally brings about prompt resolution of symptoms and radiographic signs; between attacks most patients remain well simply with inhaled bronchodilators and, if necessary, topical corticosteroids. Such patients can be taught to administer their own oral steroids when an exacerbation starts and to attend clinic for a chest film when they feel that they have recovered. It is the author's experience that if the diagnosis is made at an early stage in the course of the disease, long-term administration of oral steroids is unnecessary [213]. However, rarely, patients with aspergillar sensitivity may develop progressive lung damage, sometimes in spite of long-term corticosteroids [212]. Some of these have no clinical symptoms during attacks and are not therefore in a position to know when to use corticosteroids; they may require long-term treatment with the drug. These patients probably have permanent colonization of their airways with *Aspergillus*, and in some cases this may invade locally into bronchial walls. An extreme example of this syndrome is recognized as the asthmatic form of bronchocentric granulomatosis [218] (see Chapter 40).

The rare patient with chronic persistent, rather than

(a)

recurrent acute, manifestations of bronchopulmonary aspergillosis more typically shows residual fibrosis and bronchiectasis after the acute episode has subsided and may ultimately have extensive lung destruction [212,214] (Fig. 21.10). The clinician must be wary in the treatment of this condition since although corticosteroids are necessary to suppress the allergic manifestations, too high a dose may promote further local tissue invasion and damage. Nevertheless, in general, treatment depends on the long-term administration of adequate doses of corticosteroids, usually 10mg prednisolone daily or more, to suppress recurrences of pulmonary infiltrates [219]. If there is evidence of increasing lung damage in association with persistent bronchial colonization with *Aspergillus*, a trial of antifungal treatment is justified. This is particularly

important because amyloidosis has been described as a complication of chronic allergic aspergillosis [220]. Preliminary studies of the long-term administration of ketoconazole have suggested that this drug or one of its derivatives may be worth further investigation [221]. If during an acute episode the patient fails to respond to corticosteroids and local invasion is suspected, treatment with amphotericin is justified.

In passing, it should be noted that the syndrome of allergic bronchopulmonary mycosis, which is identical clinically to aspergillosis, may be caused by a number of other fungi as well as by several different species of *Aspergillus*; *Candida* spp., *Curvularia* spp., *Dreschlera* spp. and *Pseudallescheria boydii* are four such organisms, and doubtless others will be described [222,223].

### Mycetoma

Mycetoma is the name given to a mass of fungal hyphal material growing in a lung cavity. The usual organism is *A. fumigatus* and thus the lesion is usually called aspergilloma [224,225]; however, other fungi and other species of *Aspergillus* may occasionally be found. In most patients there is pre-existing lung disease, although the condition may occasionally arise in apparently normal lung or may be the consequence of an aspergillar pneumonia [226]. The most common predisposing conditions are old tuberculous cavities and the bronchiectasis associated with upper lobe fibrosis in chronic sarcoidosis, allergic alveolitis, ankylosing spondylitis or rheumatoid disease. Other conditions in which mycetoma has occurred include pulmonary infarcts [227], pneumonia, lung abscess and bullae.

Many mycetomas cause no symptoms and are simply noticed on radiography as the typical dense rounded shadow containing a crescentic lucent area, which outlines the top of the fungus ball and the upper part of its sur-

rounding cavity (Fig. 21.11). The patient usually has strongly positive IgG precipitins to *Aspergillus* (though not necessarily to *A. fumigatus*) [181,225]. There is sometimes also a positive immediate skin-test reaction. Some studies have commented on the frequency of associated asthmatic symptoms, although whether this is because asthmatic patients are more liable to harbour the organism or that the aspergilloma provokes the asthma is not clear. These patients may also show the features of bronchopulmonary aspergillosis.

Mycetomas are commonly multiple and usually occur in the upper zones of the lungs. They occupy the cavity and do not grow, except when they form in the course of invasive aspergillosis or when they complicate an infarct or pneumonia. Occasionally they may disappear spontaneously by lysis and this should be borne in mind when assessing the results of treatment [224,228]. There are two important complications of the condition, haemorrhage and invasion [229,230]. Haemorrhage may be trivial or exsanguinating, though most patients with severe bleeds have had smaller ones before. The combination of

**Fig. 21.11** Tomogram of patient with chronic sarcoidosis showing mycetoma in old tuberculous cavity (arrowed).

haemorrhage with the previous lung damage frequently associated with mycetoma may constitute a serious emergency. Invasive aspergillosis only rarely complicates mycetoma, but might be anticipated if such patients require corticosteroid or immunosuppressant therapy.

The appropriate management of mycetoma has been much debated [229]. The clinical outcome is determined more by the underlying lung disease than by the fungal lesion, but severe haemorrhage occurs in up to one-quarter of patients and causes death in about 5%. It is not easy to predict which patients will suffer this fate, although those with recurrent moderate-sized haemoptyses must be regarded as being at greatest risk. It is therefore logical to attempt curative treatment in such patients while adopting a more conservative line of management with asymptomatic subjects or those with only occasional and minor haemoptysis.

Curative treatment, in the form of surgical resection of the mycetoma (or mycetomas), is likely to be suitable for only relatively few patients because of the hazard of operating on subjects with severe lung disease and functional impairment [181]. It has an appreciable mortality, due to haemorrhage, bronchopleural fistula, pleural infection with *Aspergillus* and respiratory failure [224,231–233]. However it offers the only hope of removing both cavity and mycetoma. Preoperative bronchial arteriography and selective embolization, and the use of staplers in the resection, may decrease the risks of operation [234,235].

If resection is thought inadvisable, severe haemorrhage may be arrested by bronchial artery embolization or by radiotherapy [236]. Fungus may also be eradicated by cav-

ernoscopic evacuation followed by irrigation of the cavity with antifungal drugs or gentian violet and sometimes simply by local administration of antifungals into the cavity [237,238]. Cavernostomy, an earlier procedure in which the cavity is exteriorized on to the chest wall and irrigated with antifungal agents, seems to be attended by a high risk of death from bleeding or infection [229]. There have been occasional reports of eradication of fungus by treatment for prolonged periods with oral itraconazole, and this drug might be considered when other methods are thought to be too risky [239].

If the fungus becomes invasive, the patient usually shows symptoms of fever, malaise and increased cough. The organism would be expected to be found in the sputum in hyphal form and the chest film shows extension of consolidation from the original lesion. Such patients require antifungal chemotherapy. However, systemic antifungal therapy has not been shown to be of benefit in mycetoma without evidence of invasion. A scheme for the management of mycetoma is given in Table 21.3.

**Table 21.3** Management of mycetoma.

No symptoms:	leave well alone
Minor haemoptyses:	symptomatic treatment
Larger haemoptyses:	elective treatment, i.e. bronchial arteriography and resection or cavernoscopy, fungal evacuation and irrigation
Massive haemoptysis:	embolization or radiotherapy followed by elective treatment as above

### Invasive aspergillosis

Invasive aspergillosis is a disease of the immunosuppressed, particularly of those with defective granulocyte function. Thus it affects patients with acute leukaemia, patients on high doses of corticosteroids and children and young adults with chronic granulomatous disease [188,240,241]. It is also seen in patients immunosuppressed after transplantation of bone marrow or solid organs [242,243]. It is less common in AIDS, occurring as a late and usually fatal complication, sometimes manifesting as a necrotizing tracheobronchial infection [244–246]. It may also occur in a wide variety of other clinical situations, for example following influenzal or other pneumonia, pulmonary infarction, treatment of chronic air-flow obstruction with corticosteroids and resection of aspergilloma [247–250]. Very occasionally it may appear to occur *de novo* [251].

Again, it should be stressed that there is a spectrum of invasiveness. In some patients there may be a rather slow progression of local invasion of lung from a site at which the organism is primarily a saprophyte; for example infarcts may be invaded while adjacent living tissue is unaffected [227]. At the other extreme, some patients with acute leukaemia or on corticosteroids may suffer a fulminant course with extensive necrotizing pneumonia and widespread dissemination to brain, liver, kidneys, heart and other organs [240].

The diagnosis is usually suspected on clinical grounds. Thus, in a patient at risk, the development of fever and progressive pulmonary shadowing of a localized pneumonic type should arouse suspicion, though clearly other possible organisms should be considered. The white cell count and precipitating antibodies are rarely helpful in the acute illness but the presence of hyphae in sputum is a strong indication of the cause. Repeated culture of *Aspergillus* from sputum also gives strong support, although sputum may be culture-negative in invasive disease and there may not be time to wait for repeated cultures. Since several *Aspergillus* spp. produce oxalic acid, the presence of this material and a low pH in the sputum has been suggested as a simple diagnostic test [180]. However, it seems unlikely to be sufficiently specific or sensitive. Strong support for the diagnosis also comes from the development of apparent mycetomas on the chest film [226] (Fig. 21.12). These result from infarction of infected tissue (probably due to vascular invasion by the fungus), cavitation and retraction of the infarct [240]. The rapid development of such lesions may be taken as almost pathognomonic of invasive fungal infection. In leukaemic patients, it is interesting that the cavitation occurs in subjects in whom the granulocyte count is recovering, and may be complicated by life-threatening haemorrhage [252]. Those in whom the white cell count remains low after treatment show widespread dissemination without cavitation and die rapidly. In many cases it is necessary to

**Fig. 21.12** Bilateral areas of consolidation, several containing fungus balls, in an immunosuppressed patient with invasive aspergillosis.

make the diagnosis by biopsy of the involved lung, either by transthoracic needle or via the transbronchial route (Fig. 21.13). The course of untreated invasive disease is progressive. Both local and disseminated spread may cause death. Urgent treatment is therefore necessary and intravenous amphotericin combined with ketoconazole is recommended.

### Mixed syndromes

It should be clear from the foregoing that the above syndromes are not infrequently combined in the same patient. Thus the author has seen locally invasive aspergillosis successfully treated only to be followed by the development of mycetoma, asthma and allergic aspergillosis, and conversely allergic aspergillosis converted (probably by high-dose corticosteroids) into invasive disease. Mycetoma may be complicated by asthma, and allergic aspergillosis by mycetoma. The clinician should keep an

open mind when *Aspergillus* is found in the lung and be prepared to treat both allergy and infection if necessary.

## Candida

### Aetiology

*Candida* spp. are imperfect forms of the ascomycete genera *Saccharomyces* and *Pichia*. Most species, including the most important, *C. albicans*, are commensals in the mouth and gastrointestinal tract of humans. They are held in check by an intact mucosa and only become pathogenic when mucous membrane or skin is damaged or when the body's defences are impaired. They show some resistance to attachment by polymorphonuclear leucocytes, but are normally phagocytosed readily and are also susceptible to attack by T lymphocytes and macrophages [253–256].

Disease occurs as a result of local invasion of damaged skin or mucosa, aspiration into lung or introduction into

**Fig. 21.13** (a) Lung biopsy from patient with leukaemia showing hyphae in necrotic tissue to the left and an inflammatory reaction on the right (haematoxylin & eosin  $\times 90$ ). (b) Higher magnification of the same biopsy showing septate branching hyphae of *Aspergillus* sp. (Grocott  $\times 360$ ).

the tissues or bloodstream. Thus, surgical operations and indwelling intravenous cannulae can lead to disseminated candidiasis, whereas local disease may manifest as thrush, oesophagitis, lung abscess or infection of skin burns. Infection is promoted by diabetes, malnutrition, immunosuppression and, in the case of local infection, by the use of broad-spectrum antibiotics that remove competing bacteria.

### Clinical features

Lung involvement with *Candida* is rare and usually takes the form of patchy pneumonic shadowing associated with fever and tachypnoea in a debilitated or diabetic patient [257–260]. Lung abscess may occur. In cases without dissemination to other organs it is probably more usually caused by aspiration from the mouth or gastrointestinal tract [261]. Diffuse finely nodular dissemination may occur with haematogenous spread in the immunosuppressed and those undergoing cancer chemotherapy. The pathological features are bronchopneumonia with haemorrhage and necrosis.

The more familiar manifestations of candidal infection are thrush, seen not infrequently in patients on broad-spectrum antibiotics and inhaled corticosteroids, and oesophageal candidiasis, seen in debilitated patients with oral thrush. Disseminated disease involves any organ of the body and occurs in patients with acute leukaemia, *Candida* endocarditis and immunosuppression due to drugs used to prevent rejection after transplantation or for treatment of tumours [243,262,263]. Mucocutaneous candidiasis is an increasing problem with the rapid increase in the number of AIDS patients [264].

### Diagnosis

Pulmonary candidiasis is only diagnosed reliably by demonstration of the organism in lung tissue. Culture from sputum is of no value in view of the organism's normal habitat [183,265]. The yeasts, budding pseudohyphae and true hyphae may be demonstrated in tissue as Gram-positive organisms and may be cultured on routine bacterial media; special fungal media are not required. Demonstration of fungaemia and funguria may be suggestive of the diagnosis of disseminated disease but is not necessarily evidence of pathogenicity. Serological tests are not regarded as having much value in diagnosis.

### Management

Local oral and oesophageal infection can be managed most satisfactorily by amphotericin lozenges, sucked slowly five or six times daily. It is important to do this with the dentures removed. The condition can usually be prevented in asthma patients if they rinse their mouth and

throat after using inhalers. Lung infection and disseminated disease should be treated by a combination of amphotericin and ketoconazole as for aspergillar disease [258].

### *Pneumocystis* (see also Chapter 52)

#### *Pneumocystis carinii* and its epidemiology

*P. carinii* has been found in the lungs of humans and a wide range of animals [266]. Studies of antibody to *P. carinii* in children have shown a progressive rise in prevalence from birth until, at the age of 4 years, about two-thirds of normal children have a titre of 1/16 or more [267]. The organism has a life cycle involving an amoeboid trophozoite of about 2–5 µm, a somewhat larger pre-cyst, and a cyst in which up to eight sporozoites are formed [268,269]. These are liberated as trophozoites, which are capable of binary fission. Morphologically it has been thought to be a protozoon, and this has found support from its response to pentamidine and its failure to respond to antifungal drugs. However, molecular biological studies have shown its genome to have much more in common with fungi than with protozoa, hence its presence in this chapter [270,271]. It first came to prominence as a cause of severe pneumonia in malnourished infants in eastern Europe in the years following the Second World War [272,273], and subsequently was shown to cause a similar syndrome in immunosuppressed patients following treatment for acute leukaemia or other neoplasms [274]. Latterly, it has been recognized as the most important pathogen infecting the lungs of patients with AIDS, and is now the main cause of death in such patients [275,276]. While transmission of the organism from person to person has not been clearly demonstrated, there is good evidence of airborne transmission by droplets in the experimental immunosuppressed rat and mouse models [277,278]; studies of lungs of people without *Pneumocystis* pneumonia have failed to demonstrate the organism using sensitive molecular techniques [279]. It seems therefore that *Pneumocystis* is an environmental organism acquired by inhalation that only gains a foothold in the immunosuppressed and people suffering severe protein deficiency. The common factor is almost certainly suppression of T-lymphocyte function.

### Clinical features

*Pneumocystis* pneumonia occurs predominantly in infants in the first few months of life and in immunosuppressed adults and children. Originally seen most frequently in malnourished children and in patients being treated with immunosuppressant drugs for malignant disease [266,280], it is now recognized especially in sufferers from AIDS [279].

The illness usually starts with fever and cough followed

by increasing tachypnoea, the onset often being quite sudden, over a few days, in patients immunosuppressed by drugs but more insidious in patients with AIDS [281]. Inspiratory crackles are audible in a minority of patients and wheezes are rarely heard, the airways being unaffected. The chest film is almost always abnormal [282], usually showing a bilateral interstitial pneumonitis, ultimately leading to diffuse ground-glass opacification with air bronchograms. This may initially be perihilar in distribution, later spreading throughout the lungs (Fig. 21.14). These features, while indicative of a diffuse pneumonitis, are not diagnostic of *Pneumocystis* infection. The blood gases usually show increasing hypoxaemia with hypocapnia, and the carbon monoxide diffusing capacity is reduced. In the absence of treatment the disease is progressive and commonly fatal.

The condition in malnourished infants is somewhat different in presentation, usually coming on rather insidiously over a few weeks. There may be cough and associated diarrhoea but usually no fever. The infant shows signs of respiratory distress and becomes cyanosed. Again, auscultatory signs are sparse [283].

### Diagnosis

In general, the diagnosis requires demonstration of the organism in the lungs in a patient with consistent clinical features. Suspicion is aroused if an immunosuppressed patient or one with risk factors for AIDS has persistent

fever, even if the chest radiograph is normal. In this circumstance, a positive gallium scan may be the first indication of pulmonary disease [284–286]. The organism is demonstrated by staining induced sputum, bronchoalveolar lavage fluid, brushings or lung biopsy with Gomori's methenamine–silver nitrate stain, when cysts show as dark brown (Fig. 21.15). Trophozoites and sporozoites may be shown by Giemsa or polychrome methylene blue stains. However, these traditional methods result in a proportion of positive diagnoses being missed and newer techniques give a higher yield, for example monoclonal antibodies in immunofluorescence tests and DNA amplification with ethidium bromide staining; both techniques have been shown to be of high sensitivity and specificity in diagnosis on both induced sputum and bronchoalveolar washings [287,288]. In view of the poor physical condition of these patients, the simplest procedures should be tried first. It is encouraging to note that induction of sputum production by a 10–20 min inhalation of 5% saline through an ultrasonic nebulizer may allow demonstration of the organism by one or other of these techniques in a high proportion of patients, thus obviating the need for bronchoscopy and biopsy [288–290].

### Treatment

The organism is sensitive to co-trimoxazole (trimethoprim and sulfamethoxazole), dapsone–trimethoprim, and pentamidine. The standard therapy in drug-immunosup-

(b)

**Fig. 21.15** (a) Section of lung biopsy from bone marrow transplant patient showing alveoli filled with the characteristic foamy and granular infiltrate of *Pneumocystis pneumonia* (haematoxylin & eosin  $\times 230$ ). (b) Some tissue stained to show the typical cysts of *Pneumocystis carinii* (Grocott methenamine-silver  $\times 900$ ).

pressed patients is co-trimoxazole (sulfamethoxazole 100 mg/kg and trimethoprim 20 mg/kg daily) in divided doses [291,292], but lower doses are necessary when renal failure is present. A 10–14 day course is usually sufficient, although in patients with AIDS it may be necessary to give more than one course or to continue treatment for a month or more as there is evidence that organisms persist in the lung and relapse occurs in patients treated only for 2 weeks [281,293]. Moreover, these patients appear to be unduly sensitive to the co-trimoxazole, often developing rash, fever and leucopenia, and for this reason lower doses or alternative regimens have been tried. It is now conventional to treat AIDS patients according to the severity of the pneumonia [279]. In mild cases without hypoxaemia, oral dapsone-trimethoprim for 21 days is usually effective. In severe cases with a  $PaO_2$  of 8 kPa (60 mmHg) or below, intravenous co-trimoxazole or pentamidine should be used together with high-dose corticosteroids. Side-effects of pentamidine include leucopenia, hypoglycaemia, uraemia and pain at the injection site. Apart from

the pain, these are not particularly common in AIDS patients. The use of these and other second-line drugs in the management of AIDS pneumonia are discussed in detail in Chapter 52.

Such treatment given early may be expected to produce a cure in most patients, although relapse may occur, particularly in patients with AIDS. However, it should be noted that immunosuppressed patients may have several coexisting pulmonary infections, and a combination of *Pneumocystis* with cytomegalovirus or mycobacterial infection is not uncommon. If treatment is successful, the lungs may be expected to revert to normal and fibrosis does not appear to be an important complication. This has been shown to be the case in the less confusing situation of children who have developed the infection in the course of cytotoxic therapy for leukaemia and lymphoma; all survivors in one large study had normal lung function within 6 months of completing therapy for *Pneumocystis pneumonia* [294]. Because of the frequency of infection and relapse in AIDS patients, prophylactic therapy is used when the

CD4 count falls to  $0.15 \times 10^9/L$ . Either oral co-trimoxazole (trimethoprim 160 mg and sulfamethoxazole 800 mg daily) or inhaled nebulized pentamidine 300 mg monthly are used. Chemoprophylaxis is also given for up to 1 year to children treated for acute lymphoblastic leukaemia or receiving transplants, using appropriate doses of co-trimoxazole.

### Other rare fungal opportunist pathogens

In immunosuppressed or debilitated patients, particularly those on steroids, and occasionally in diabetics, infections with other fungi may occur. Three zygomycetes, *Mucor*, *Absidia* and *Rhizopus*, are saprophytic organisms familiar as the mould that grows on bread. They may rarely be responsible in immunosuppressed subjects for mucormycosis, a disseminated disease with a predilection for invading sinuses and brain; diffuse pneumonitis may occur, particularly in patients being treated for lymphoma and leukaemia. The pathological lesion is usually fungal invasion of vessels with infarction of lung tissue [295,296].

They may also be discovered as the cause of pulmonary granulomas or mycetoma [297,298]. Diagnosis is made by demonstration of broad, non-septate hyphae in tissue samples. Spread of the organisms from contaminated air-conditioner filters has been described [299]. *Pseudallescheria boydii* (or, in the imperfect state, *Monosporium apiospermum*) is a soil saprophyte that has been described as producing mycetomas as well as having caused bronchial colonization and lung abscess in the immunosuppressed [300,301]. *Penicillium* spp. are ubiquitous saprophytes that produce large numbers of airborne spores, yet only very rarely have they been associated with disease. Spores may provoke asthma or allergic alveolitis (e.g. cheesewashers' disease due to *P. casei* [302]). Very occasional examples of pneumonitis and disseminated disease in the immunosuppressed have been described [303]. Similarly, *Torulopsis glabrata*, a yeast-like organism that is a commensal in the female vagina, may occasionally occur as a pathogen, causing pneumonitis and disseminated infection in patients receiving cancer chemotherapy [304].

# PARASITIC DISEASES

ANTHONY SEATON

Animal parasites, though a major cause of morbidity and mortality worldwide, are only rarely direct causes of lung disease (Table 22.1); those that belong to the phyla Protozoa, Nematoda, Platyhelminthes and Arthropoda. Among the protozoal diseases in which lung involvement may occur are amoebiasis, malaria and toxoplasmosis. In Western countries, a number of these parasites now feature among those multiple organisms infecting the immunocompromised. Of the platyhelminths, infection with *Schistosoma* may lead to pulmonary hypertension while paragonimiasis and hydatid disease involve the lungs directly. Cysticercosis may cause diagnostic confusion on chest films. Many of the nematode worms may provoke pulmonary eosinophilia and *Toxocara* infection is associated with the symptoms of visceral larva migrans. One nematode, *Mammomanogamus*, actually lives in the bronchi. *Trichinella* is another cause of multiple calcifications in muscles that may be seen on a chest radiograph. Finally, one class of arthropod parasite appears to cause lung disease in humans, the worm-like Pentastomida, though mites are a ubiquitous and important source of antigen involved in the provocation of asthmatic attacks.

## Protozoal parasites

Pneumonia may occur as a complication of chronic debilitating diseases such as sleeping sickness (*Trypanosoma brucei*) and kala-azar (*Leishmania donovani*). Aspiration pneumonia and pulmonary embolism may result from the oesophageal dilatation and intraventricular thromboses of Chagas' disease (*Trypanosoma cruzi*) [1–3]. However, direct involvement of the lungs by protozoa occurs with severe episodes of *Plasmodium falciparum* malaria [4–6] and in infection with *Entamoeba* and *Toxoplasma*. Obliterative bronchiolitis has been described as a complication of *Plasmodium vivax* infection [7]. Lung disease due to *Pneumocystis carinii* is discussed in Chapters 21 and 52, this organism having been reclassified as a fungus.

## Thoracic amoebiasis

### *Entamoeba histolytica* and its epidemiology

The causative organism of amoebiasis is an obligatory parasite that lives anaerobically in the colon of humans, feeding on bacteria and desquamated epithelial cells [8–10]. Its prevalence in a population is dependent on the local standards of hygiene, since transmission of the organism depends on one person ingesting the cysts passed in the faeces of another. In some areas of the tropics and subtropics infection (usually asymptomatic) is widespread, whereas in Europe and North America it is rare. Nevertheless, even in developed countries poor hygiene may allow transmission of imported amoebiasis among close contacts [11], while pockets of high prevalence may be found in areas with high immigrant populations, among homosexuals (when genital infection may occur) or in long-stay institutions for the mentally retarded [12,13].

*E. histolytica* exists in two forms, the trophozoite or motile amoeba (Fig. 22.1) and the cyst. Trophozoites have pathogenic potential, although they may live in the colon as commensals. The commensal amoeba is responsible for cyst formation, acquiring a rigid wall that can protect it from gastric juice and chlorine for example. The amoeba may divide up to twice within the cyst, but its lifespan is limited to a few days at most unless ingested by a suitable host. Excystation does not occur in the colon of the original host or in the outside environment, though it may occur in culture media at 37°C and in the bowel of the recipient.

The disease amoebiasis results from a change in behaviour and structure of the commensal amoebae or, more probably, from a change in the predominant type of amoeba to a larger and more active organism, which invades through the mucous membrane and ingests red blood cells rather than bacteria. The reasons for this change are not clear, although it is more likely to occur if the patient is malnourished, alcoholic or has other bowel disease.

**Table 22.1** Parasites causing thoracic disease.

Phylum	Class	Genus	Disease
Protozoa	Mastigophora	<i>Trypanosoma</i>	Chagas' disease
	Rhizopoda	<i>Entamoeba</i>	Amoebiasis
	Sporozoa	<i>Plasmodium</i>	Malaria
		<i>Toxoplasma</i>	Toxoplasmosis
Nematoda (roundworms)	Aphasmidia	<i>Trichinella</i>	Trichinosis
	Phasmidia	<i>Ascaris</i>	Pulmonary eosinophilia

### Clinical features

Most carriers of *E. histolytica* are free of symptoms. Invasion of bowel wall by the organism results in amoebic dysentery, with abdominal pains, colonic tenderness, diarrhoea and fever [14–18]. The symptoms can range from a mild transient abdominal disturbance to acute abdomen with peritonitis or toxic megacolon. Involvement of the liver, which is the usual precursor of lung disease, may occur in the acute attack but usually only becomes apparent months or years later; indeed many patients with amoebic hepatitis give no history of previous bowel disease.

Pulmonary involvement usually results from direct spread of a hepatic abscess through the diaphragm. The liver lesion develops from the coalescence of multiple small abscesses as a result of embolism of amoebae

through the portal vein. The lesion is most usually found in the right lobe and pathologically consists of necrotic liver surrounded by active amoebae. The amoebae are capable of detaching and lysing adjacent cells, and the abscess can extend across tissue planes. The patient with an amoebic liver abscess usually feels ill, loses weight and has fever, tender hepatomegaly and rib tenderness. The lesion may point through the skin or, more commonly, rupture into the lung or the pleura (see Plate 22.1, facing p. 630). Such rupture is usually associated with cough, sometimes productive of 'anchovy sauce' sputum if a hepato-bronchial fistula is present. There may be pain, sometimes referred to the right shoulder. Much less commonly, metastatic lung abscesses may occur as a result of rupture of a liver abscess into the hepatic veins. In such patients the clinical features are no different but the lesions may be multiple and occur anywhere in the lung. A liver abscess may also rupture into the pericardium and may cause acute or gradually progressive signs of tamponade [19]. Involvement of lung or pericardium is a serious complication of amoebic infection, particularly as a high proportion of patients are already debilitated by malnutrition or alcoholism. If treatment is not initiated promptly the infection may often prove fatal.

### Radiographic appearances

Liver abscess is frequently associated with elevation of the right hemidiaphragm; some inflammatory changes may be seen at the right lung base, together with a small pleural effusion, before rupture occurs [20]. Rupture may be accompanied by a large pleural effusion, streaky consolidation or abscess formation in the right lower lobe [21]

**Fig. 22.2** Chest film of patient in Plate 22.1 showing amoebic lung abscess and pleural effusion.

(Fig. 22.2). Enlargement of the cardiac shadow may indicate rupture into the pericardium. Metastatic amoebic abscess or abscesses are indistinguishable radiologically from other causes of lung abscess.

### Diagnosis

The key point in diagnosis is to suspect amoebic infection in anyone who has visited areas where such disease is endemic and who is likely to have been exposed to poor food hygiene. Such patients with appropriate physical and radiological signs may need to be given a therapeutic trial of antiamoebal treatment if diagnostic facilities are poor. Motile amoebae should be sought by an experienced microscopist in fresh, warmed stool specimens and in anchovy sauce sputum or the last aspirates from liver abscess, and can be typed by the electrophoretic pattern of their zymodemes or by DNA probes. Cysts may be found in stools. Serological tests, including indirect haemagglutination and gel diffusion for precipitating antibody, are frequently positive in the invasive stage of the disease [22–24]. Liver abscess may be demonstrated by gallium scan, ultrasound or conventional isotope scan; in many circumstances, diagnostic liver aspiration remains the most reliable way of making the diagnosis.

### Management

As with many tropical and subtropical diseases, prevention of amoebiasis depends on good hygiene. The traveller should avoid local water, salads and cooked food from markets. The treatment of choice is metronidazole 800 mg three times daily for 5–8 days [25]. Aspiration of liver, lung or pericardial abscesses may also be necessary. If this drug is not available, a combination of chloroquine and emetine may be necessary. Other regimens may be effective and the advice of a specialist in tropical diseases should be sought. Other drugs include diloxanide and diiodohydroxyquin, which eliminate persistent bowel organisms but are not active against tissue amoebae. Chloroquine is effective against organisms in the liver, while dihydroemetine is useful because of its rapid action in seriously ill patients. Side-effects may occur: dihydroemetine is cardiotoxic, chloroquine may cause nausea and rashes, and metronidazole also causes nausea and a disulfiram-like syndrome with alcohol.

### Toxoplasmosis

#### *Toxoplasma gondii* and its epidemiology

*T. gondii* is an obligatory intracellular parasite found widely in humans and animals. A high proportion of the human population shows evidence of past infection, although a history of disease is rare. The organism exists in three forms. Tachyzoites are crescentic or oval bodies about 5 µm long that are able to penetrate living cells, where they divide repeatedly and either form a tissue cyst or disrupt the cell. The tissue cyst is a walled structure up to 200 µm in size containing many organisms, found particularly in brain, heart and skeletal muscle. It is the form in which infection is transferred between meat-eaters, including those humans who prefer their meat undercooked. The third form of *T. gondii* is the oocyst, which is a 10-µm ovoid body formed only in the intestine of members of the cat family [26]. Cats are infected by eating animals containing either tachyzoites or tissue cysts; these develop in the gut into oocysts, which in turn are passed in the faeces where they are a source of infection to other animals. Humans are usually infected either by eating infected meat or *in utero* from a maternal infection acquired in pregnancy [27]. Antibody studies have shown that up to 70% of adults have at some time been infected, although only a small proportion of these infections have caused clinical disease [28,29].

### Clinical features

Toxoplasmosis causes three main syndromes: congenital infection, acute infection and disseminated disease in the immunosuppressed. Congenital infection does not

usually affect the lung, the disease being primarily manifest in the eyes and central nervous system. Similarly, acute toxoplasmosis in immunocompetent adults rarely involves the lung, but causes a glandular fever-like syndrome. In contrast, infection in those who are immunosuppressed, whether by drugs, malignant disease or AIDS, frequently causes diffuse pneumonitis [30–32]. Involvement of the central nervous system with encephalitis is also common [33]. Disease may occur either as a result of a recent infection or from breakdown of a previously acquired, latent, infection.

There are no features of pulmonary toxoplasmosis that enable a clinical diagnosis to be made with confidence. The patient is usually febrile and breathless, and the radiograph may show diffuse or localized hazy or diffuse nodular infiltrates [31,34]. In the immunosuppressed there may be rash or lymph node enlargement and, more commonly, evidence of meningoencephalitis. There is, of course, other clinical evidence of the primary condition responsible for immunosuppression.

### Diagnosis

The diagnosis of pulmonary toxoplasmosis depends on demonstration of the organism in the lung [34]. Pathological studies have shown tachyzoites to be sparse and mainly intracellular in areas of acute pneumonitis and numerous both within and outwith cells in necrotic areas [35]. Fluorescent antibody tests are helpful in identification of the organism. The clinical features of infection do not differ from those of other opportunist infections in immunosuppressed patients and studies of toxoplasma antibody in such patients are of little value in that changes usually do not occur or, if they do, reflect infection elsewhere than in the lung. Thus the hope is that the organism may be demonstrated in lung biopsy or bronchoalveolar lavage specimens. The latter method, being relatively non-traumatic, is being used increasingly in such sick patients [36,37]. Specific stains for the organism and for antigen have been introduced and these may well increase the sensitivity and specificity of the diagnosis of pulmonary toxoplasmosis.

### Management

The condition is fatal in immunosuppressed patients unless treated and therefore a therapeutic trial of therapy is desirable when clinical suspicion is high, even if the diagnosis cannot be confirmed. It is recommended that treatment be continued for 1 month after clinical resolution, which may mean several months of therapy. The most effective regimen is probably a combination of sulfadiazine (sulphadiazine) 100 mg/kg daily orally up to a maximum of 8 g daily and pyrimethamine 100 mg daily for 2 days then lower, intermittent doses [38,39]. The latter

drug is a folic acid antagonist and adverse effects on the bone marrow may be prevented by folinic acid 10 mg on alternate days. Other side-effects of the sulphonamide also occur frequently, making satisfactory treatment something of an ordeal for the patient.

## Malaria

### Malarial parasites and their epidemiology

Malaria is second only to tuberculosis in importance as a cause of illness and death worldwide [40]. Some 170 million people contract the disease annually, of whom over 1 million die. Lung disease is a late feature, occurring almost exclusively in severe cases of *Plasmodium falciparum* infection. The life cycle of the parasite depends on the presence of both humans and anopheline mosquitoes. The mosquito obtains mature gametocytes in red corpuscles from the blood of humans and these undergo sexual fusion in the insect's gut prior to penetrating the gut wall to form an oocyst. This liberates into the blood many sporozoites that migrate to the salivary gland, from where they are injected into the next person on whom the insect feeds. The next part of the cycle in humans involves rapid transfer of sporozoites to hepatic cells where they first multiply as tissue schizonts and whence they are released into the bloodstream as merozoites; these adhere to and invade red blood cells wherein they multiply again as blood schizonts and are released into the blood in a cyclical manner as merozoites to reinvade further erythrocytes (Fig. 22.3). Some remain in red cells to develop into gametocytes, and thus complete the cycle by being taken in by a mosquito. The periodic rupture of red cells to liberate merozoites is accompanied by release of cytokines that are responsible for the periodic symptoms of the disease.

Fig. 22.3 Blood film from patient who died of cerebral malaria showing unusually heavy load of *P. falciparum* parasites in red cells. (Courtesy Dr Andrew Seaton.)

Malaria is endemic throughout the tropics, save for the southern Pacific islands. In tropical Africa and Papua New Guinea almost everyone is infected in childhood and it is at this age when most illness and death occurs, whereas in many other parts of the tropics the pattern of the disease is more epidemic, outbreaks occurring across all ages on an area basis. For visitors to the tropics, infection by *P. falciparum* can occur anywhere from a mosquito bite, and disease may appear between 1 week and 1 year later, though the large majority of infections present within 3 months. Infection with *P. vivax* and other less severely pathogenic species commonly takes longer to present and may well occur more than 1 year after return from the endemic region.

### Clinical features

Lung involvement occurs almost exclusively in patients with *P. falciparum* malaria [41–43]. The patient has a history of several days of non-specific malaise, headache and muscular pains before the first paroxysm of severe fever. Usually the condition has been untreated for several days and other serious manifestations, such as cerebral malaria and blackwater fever, may be present. At this stage, the patient is often hypotensive and extremely ill. The respiratory complications typically occur after a day or two of treatment, the patient developing cough and tachypnoea. Crackles are heard in the lungs, the chest film shows signs of pulmonary oedema and hypoxaemic respiratory failure is present. Not surprisingly, the condition is commonly fatal.

The pathology of the condition is that of adult respiratory distress syndrome and pulmonary oedema. While therapeutic fluid overload and low serum albumin levels may contribute, it seems likely that the primary pathogenesis is an inflammatory reaction provoked by arrest of parasitized red cells in pulmonary capillaries. Red cells containing the earlier ring forms of the parasite are less deformable and therefore more readily held up in the pulmonary circulation; they are also more resistant to antimalarial drugs at this stage in their life cycle [6,42,44,45].

### Management

This serious emergency should be managed with the advice of someone experienced in tropical medicine and intensive care if at all practicable. Intravenous quinine is the mainstay of treatment, given as the dihydrochloride at 20 mg/kg as a loading dose over 4 h and then 10 mg/kg infused in isotonic saline over 4 h, repeated 8-hourly [46]. Intermittent positive pressure ventilation, often with high inspired oxygen concentrations, is usually necessary. Care needs to be exercised to avoid fluid overload, but red cells may need to be transfused to correct anaemia.

## Nematode parasites

*Ascaris*, *Toxocara* and various filarial worms are associated with the syndrome of tropical eosinophilia. Two nematodes, *Dirofilaria* and *Mammomanogamus*, may cause lung disease directly, while *Trichinella* may cause multiple calcified lesions in the chest wall.

### Pulmonary eosinophilias

These conditions are described in Chapter 38. There is a spectrum of syndromes related to nematode infestation, variously grouped as transient pulmonary eosinophilia or Loeffler's syndrome, visceral larva migrans, and persistent tropical pulmonary eosinophilia. The first is usually caused by *Ascaris lumbricoides*, though *Ancylostoma*, *Strongyloides* and a number of other worms may cause it. Visceral larva migrans is associated with *Toxocara* infection, while tropical eosinophilia is related to infestation by various filarial worms.

### The parasites and their epidemiology

*Ascaris lumbricoides* is found throughout the temperate and tropical parts of the world and is a frequent parasite of humans, especially in areas of poor sanitation. It grows to 35 cm in length, the female being rather longer than the male. The eggs, which are oval and up to 70 × 50 µm in size, are passed in the faeces of the host and require a few days in moist soil to mature. When ingested by another person they hatch in the duodenum where the larvae penetrate the wall into the bloodstream and pass through the heart into the pulmonary capillaries. There they penetrate into alveoli, migrate up the bronchi and are swallowed, and develop into adult worms in the small intestine. Within 2 or 3 months the cycle is complete, the adult worms producing vast numbers of their own eggs. They survive for about 1 year in the intestine, where they may cause no symptoms or may provoke abdominal pains, biliary colic or nausea and vomiting. Pulmonary eosinophilia accompanies the period of larval migration through the lungs.

The hookworms, *Ancylostoma duodenale* and *Necator americanus*, are also widely distributed in tropical and temperate regions. The ova hatch in moist soil and develop for several weeks in that environment, moulting to form an infective larva. This waits in surface moisture for contact with human skin, which it penetrates and passes into the bloodstream and thence to the pulmonary capillaries where, like *Ascaris*, it migrates into the alveoli. It then works its way up into the trachea, is swallowed and matures by attachment to the intestinal mucosa, feeding on blood and tissue juices. Pulmonary eosinophilia may accompany the lung migration, while iron deficiency anaemia is the most serious consequence of the intestinal parasitism.

*Strongyloides stercoralis* has a similar distribution to that of hookworm. It may live free in the environment for a generation or two, but eventually produces infective larvae that penetrate the skin and migrate in the same way as hookworm, occasionally causing pulmonary eosinophilia. Heavy intestinal infections can cause malnutrition, diarrhoea and blood loss. Infective larvae can be produced in the intestine, permitting a cycle of autoinfection; in this hyperinfection syndrome, which occurs particularly in the immunosuppressed, direct lung involvement can occur.

The filarial worms that parasitize humans include *Wuchereria bancrofti*, which causes elephantiasis, and *Loa loa*, which causes Calabar swellings. They are found predominantly in Africa and tropical parts of Asia. These and other filariae are transmitted by insect intermediate hosts, which acquire the organism by feeding on the blood of an infected person and taking in microfilarial larvae. These then develop in the thorax of the insect into much larger infective larvae, which migrate to the proboscis and in turn are injected into the next person on whom the insect feeds. Further development takes place, probably in the lymphatic system, and the adult worms mature, mate and produce eggs that turn into the microfilariae. These develop a cycle of entry into the bloodstream and migration into the tissues. They probably spend part of this time lodged in pulmonary vessels, where they give rise to symptoms and allergic reactions.

*Toxocara canis* and *T. cati* are parasites of dogs and cats respectively, living in their hosts' small intestines. Their ova need to spend some time maturing in soil and develop into larvae in the intestine of the animal that ingests them. The life cycle of *T. cati* mimics that of *Ascaris lumbricoides*, with migration through the host's lung. In contrast, *T. canis* larvae migrate into the somatic tissues where they provoke the formation of granulomas. In the female dog they become active when pregnancy occurs and revert to the pattern of pulmonary migration or pass through the placenta to infect the pups. In humans, neither organism is able to complete its natural cycle. Ingestion (usually by children) of ova shed by cats, pups or pregnant bitches leads to migration of larvae to organs including lungs, liver, heart, kidney and muscles, giving rise to the syndrome of visceral larva migrans.

### Clinical syndromes

All the above parasitic infestations are associated with peripheral eosinophilia. In addition, symptoms may be associated with intestinal malabsorption, blood loss and malnutrition, and with intestinal obstruction by masses of worms. Skin rashes and urticaria may result from local hypersensitivity. Migration of larvae through the lung results in cough, breathlessness, wheeze and diffuse, often patchy, pulmonary infiltrates. In *Toxocara* infestation,

arrest of the larvae in the lungs is associated with the pulmonary component of visceral larva migrans [47–49], in which the patient's illness may range from simple blood eosinophilia to a severe disease with fever, cough, wheeze, abdominal pains and sometimes central nervous system symptoms. The patient is usually a young child, and hepatomegaly, high eosinophil count, hypergammaglobulinaemia and pulmonary infiltrates are common features. Bronchoalveolar lavage shows high proportions of eosinophils [50]. The condition usually resolves spontaneously. The microfilarial embolization of pulmonary vessels that may occur with a number of filarial worm infestations is associated with the more persistent features of tropical pulmonary eosinophilia [51,52]. The symptoms are similar to those of visceral larva migrans, with generalized malaise, fever and weight loss, together with cough, wheeze and shortness of breath. The chest film may range from normal to diffuse bilateral infiltration and a high eosinophil count ( $>3.5 \times 10^9/L$ ) is almost always present [53]. The symptoms may be present over years and may mimic asthma clinically and pneumonia or tuberculosis radiologically [54,55].

### *Strongyloidiasis*

Infestation with *Strongyloides stercoralis* is endemic throughout the tropics and subtropics, and subclinical infection is very common. It should be suspected as a cause of asthma and eosinophilia in patients from endemic areas [56]. As well as being one of the causes of tropical eosinophilia, the organism may cause a hyperinfection syndrome in which severe pulmonary disease is common [57,58]. This occurs as a consequence of arrest of larvae in the lungs and presents with general illness, urticarial eruptions on the skin and pulmonary infiltrates, often together with evidence of involvement of other systems such as malabsorption and meningitis [59]. The condition affects especially people on high doses of steroids or other causes of reduced immunity [60], though it appears not to be a particular problem in AIDS patients. The lung disease may progress to adult respiratory distress syndrome and a granulomatous interstitial pneumonitis has been described [61,62].

### Diagnosis and management

Ascariasis is diagnosed by detection of ova in the stools and treated by mebendazole 100mg twice daily for 3 days. Hookworm may be diagnosed and treated similarly, together with iron replacement if necessary. *Strongyloides* infestation is diagnosed by demonstrating larvae in stools or in duodenal aspirate and is treated with thiabendazole 25mg/kg twice daily for 3 days. Albendazole in a single dose of 400mg and ivermectin 200µg/kg have also been shown to be effective and have fewer side-effects [63,64].

Severe infections, with autoinfection, have a high mortality and longer treatment courses may be necessary, using albendazole 400 mg 12-hourly for two or more weeks. Filariasis may be diagnosed by demonstration of microfilariae in blood taken at an appropriate time or by detection of filarial antibodies. Treatment is with diethylcarbamazine 3 mg/kg three times daily for 3 weeks. This kills the microfilariae and results in relief of pulmonary symptoms; it may therefore be used as a therapeutic trial in patients with appropriate clinical features and travel history if the diagnosis has not been established. The adult worms may not be eliminated or killed by this treatment, so prevention of infection by elimination of insect vectors and avoidance of bites is particularly important.

Visceral larva migrans is suspected in children with appropriate symptoms who may have been eating soil. The diagnosis may be made by an enzyme-linked immunosorbent assay. Treatment is probably only advisable in patients with troublesome pulmonary symptoms, as the disease tends to remit spontaneously. Diethylcarbamazine or thiabendazole may be tried, usually for several weeks, but trials of ivermectin in single doses of 200–400 µg/kg have shown promise. If there is a severe hypersensitivity reaction, corticosteroids may be advisable.

### Dirofilariasis

Although not a natural parasite of humans, the dog heart worm, *Dirofilaria immitis*, may occasionally cause pulmonary disease [65–68]. It is a filarial worm usually transmitted between dogs by mosquitoes. After maturing under the skin, the worms enter the circulation and live in the animal's heart and pulmonary vessels. Accidental infection of humans may occur by mosquito bite and, though reported predominantly from the USA, is probably more widely distributed. The parasite is unable to complete its life cycle in humans but adult worms may lodge in small pulmonary arteries, causing a granuloma that presents radiologically as a peripheral patch of pneumonitis or as a coin lesion up to 5 cm in diameter. Eosinophilia is not usually present. The lesion is indistinguishable from neoplasm and is usually only diagnosed after surgical excision. The worm may be demonstrated by non-specific fluorescent whitening stains [68].

### *Mammomanogamus laryngeus*

This nematode worm has occasionally been found in the sputum or bronchial tree of humans, where it appears to provoke persistent cough [69]. Its life cycle is not known but it is probably acquired by insect bite or by eating an intermediate host. All reports have been in people who have lived in or visited the Caribbean. Symptoms respond to treatment with mebendazole 100 mg daily for 3 days.

### Trichinosis

Infection with *Trichinella spiralis* is acquired by eating undercooked meat containing larval cysts. Pork and bear are important sources in the USA, where infection is not infrequent [70]. The larvae are liberated in the stomach and develop into adult worms in the intestine. After mating, further larvae are produced that pass through the pulmonary circulation to lodge in skeletal muscles where they form cysts. The larvae eventually die in humans and the lesions may calcify, in which case they may cause diagnostic confusion on a chest radiograph until it is appreciated that they lie in the muscles of the chest wall. During the phase of larval migration, fever, myalgia, circumorbital oedema and eosinophilia may occur [71,72]. Occasionally myocarditis or pneumonia may complicate the illness, and in severe cases the myositis may mimic poliomyelitis. At least one case of ventilatory failure has been reported [73].

### Platyhelminth parasites

Representatives of two classes of platyhelminth, the trematodes and the cestodes, may cause lung disease in humans. Of the trematodes, *Schistosoma* spp. and *Paragonimus westermani* are important pathogens, while the cestode *Echinococcus granulosus* is the cause of hydatid disease. Cysticercosis, caused by *Taenia solium*, may also cause radiological opacities in the muscles of the chest wall.

### Schistosomiasis

#### The parasites and their epidemiology

Three species of *Schistosoma*, *S. mansoni*, *S. haematobium* and *S. japonicum*, are important causes of disease; they are endemic in 79 poorly developed countries and several hundred million people may be infected by one or other of them [74]. *S. mansoni* is found throughout Africa, the Arab countries, South America and some of the Caribbean, *S. haematobium* in Africa and the Middle East and *S. japonicum* in Japan, China and the Philippines. The organisms require fresh water and certain species of snail as intermediate hosts to complete their life cycles. Humans are the usual definitive host, although *S. japonicum* infects a wide variety of other exposed mammals.

Ova are excreted in the faeces or urine of humans. If they are shed into fresh water they hatch into ciliated miracidial larvae, which are able to penetrate the skin of an appropriate snail and develop into a sporocyst. This divides and the daughter sporocysts migrate to the snail's gut where they develop into cercarial larvae. These in turn are passed into the water where they swim freely and survive for several days. If during this time they come into

contact with the skin of humans, they are able to penetrate it and start the complex process whereby the life cycle is completed. Each cercaria that penetrates the skin is able to develop into one adult worm, of single sex, but not all survive the journey. On penetration, the cercaria transforms into a schistosomulum that passes into the bloodstream, through the pulmonary bed and the systemic circulation, eventually finding itself in the liver. There it develops into the adult worm and is able to migrate against the blood flow down the portal vein into the intestinal mucosa and, in the case of *S. haematobium*, through collateral vessels into the vesical venous plexus. Male and female worms mate at this site and produce enormous numbers of eggs. The mature worms may live and continue to produce eggs for many years, but the eggs need to reach the outside to restart the life cycle. A proportion of them succeed, by penetration of intestinal or bladder mucosa, but most become trapped in the local tissue or embolize in the bloodstream, setting up a granulomatous reaction that is responsible for the chronic manifestations of schistosomiasis.

### Clinical features

Penetration of the skin by cercariae, which occurs when the victim swims or bathes in fresh water in an endemic area, may cause itchy papules (swimmers' itch). This is a hypersensitivity reaction and occurs on second and subsequent exposures, though it is more common with species of *Schistosoma* that are natural pathogens of other mammals and birds. A month or two later, as the adult worms start to produce eggs, a generalized and sometimes severe episode analogous to serum sickness and called Katayama fever may occur. This also seems to be a delayed-type hypersensitivity reaction, characterized by fever, malaise, cough, aches, enlargement of liver, spleen and lymph nodes, and blood eosinophilia [75]. In massive *S. japonicum* infections this may be fatal.

Most people infected with *Schistosoma* spp. have no symptoms, the severity of disease being related to the number of worms harboured. Natural immunity does not occur, so reinfection may be frequent and such patients may develop chronic manifestations of schistosomiasis related to granuloma formation around eggs retained in tissues [76]. These lead to fibrosis, so that intestinal strictures and pseudotumours occur with *S. mansoni* and *S. japonicum* and bladder papillomas with ureteric and urethral obstruction occur with *S. haematobium*. Embolization of the portal tracts leads to periportal fibrosis, splenomegaly and portosystemic anastomoses. Systemic venous embolization leads to granuloma formation in pulmonary arterioles, which may cause solitary or multiple peripheral shadows on the chest radiograph or may lead to pulmonary hypertension and cor pulmonale [77–79]. This latter condition normally occurs as a compli-

cation of embolism of ova through portosystemic anastomoses in portal hypertension. The end-result of this can be aneurysmal dilatation of the pulmonary arteries and death from cor pulmonale. The bowel and bladder lesions are complicated by blood loss, obstructive syndromes and, in the case of *S. haematobium* infection, carcinoma of the bladder.

### Diagnosis and management

Schistosomiasis is diagnosed by finding ova in stools or urine. Since significant infection is always accompanied by the excretion of large numbers of ova, a negative finding by an experienced microscopist can be taken to exclude the diagnosis.

The infection is prevented by avoiding skin contamination by fresh water in endemic areas. Cercariae do not survive in water that has been stored more than 24 h or boiled. If the skin is contaminated, cercariae can only penetrate if it remains wet; rapid drying therefore prevents infection. There is no adequate treatment for swimmer's itch or for this initial stage of the infection. Severe Katayama fever may require suppression with corticosteroids, but it is doubtful if any antischistosomal drugs have any effect at this stage of the infestation. For chronic disease, praziquantel is effective against all species of *Schistosoma*: 40 mg/kg in one dose is adequate for *S. mansoni* and *S. haematobium* and 20 mg/kg for three doses in 1 day for *S. japonicum* [80].

Long-term control of schistosomiasis depends on improvements in disposal of urine and faeces, control of the snails by molluscicides and treatment of individuals with heavy infection. However, partial control in one area is often accompanied by spread in other areas associated with the introduction of irrigation schemes. The best hope for control is likely to be wide-scale treatment programmes and improvements in sanitation.

### Lung fluke

#### *Paragonimus* spp. and their epidemiology

There are many species of *Paragonimus* that infect humans and other flesh-eating vertebrates. The best-known is *P. westermani*, which is widely distributed throughout the Far East. Other species are found in Africa and Central and South America. The parasite is a fluke, about 1 cm in length, whose eggs are shed in the host's sputum (or faeces if the sputum is swallowed). They mature in fresh water to liberate miracidia that penetrate the first intermediate host, a snail. Several months later cercarial larvae emerge looking for a crab or crayfish. If successful, they penetrate it and form cysts in its gut and muscles. Transfer to humans or other vertebrates occurs when they eat the uncooked meat of the crustacean or drink its juices for

their supposed medicinal effect. Metacercariae excyst in the gut where the flukes develop, penetrate the wall into the peritoneum and migrate directly through diaphragm and pleura into the lung. They may go astray and end up in other tissues such as peritoneum, subcutaneous tissue, muscle or brain. Once established in the lung they reach sexual maturity and, being hermaphrodite, produce eggs. They may survive up to 10 years in the body.

### Clinical features

Many light infections are asymptomatic [81–83]. The most frequent symptoms are cough, sputum, haemoptysis and pleurisy, though the clinical features may sometimes result from involvement of subcutaneous tissues, brain or abdomen. There is blood eosinophilia and the chest radiograph may show a variety of signs, from transient infiltrates to cavities, single or multiple cysts and calcified nodules. Pleural effusions occur in almost half the patients and may be massive. CT may demonstrate multiple 5–15 mm cysts and evidence that is interpretable as worms in cysts and worm tracks [84].

### Diagnosis and treatment

The diagnosis may be suspected in someone with appropriate eating habits from an endemic area who has chronic cough, expectoration, eosinophilia and lung shadows. Increasing numbers of cases have been described in refugees to the West from South-East Asia, and the long survival of the parasite means that disease may present anywhere in the world long after leaving the site of infection. The diagnosis may be made by detection of the eggs in sputum or, occasionally, by finding an expectorated fluke. The discovery of the condition is credited to Sir Patrick Manson who when working as a young doctor in China had the curiosity to examine the sputum that a local mandarin had hawked up onto the carpet of his consulting room—a useful lesson to all doctors! However, in early or late cases eggs may not be found and complement fixation tests are generally a reliable means of confirming the diagnosis [81]. In patients with pleural effusion, the fluid should be examined for ova and detection of IgG and IgE specific to the parasite is probably a sensitive diagnostic test [85]. Treatment is with praziquantel 60 mg/kg daily in three divided doses for 1–3 days [86], together with aspiration of any pleural effusion.

### Hydatid disease

#### *Echinococcus granulosus* and its epidemiology

Humans are in the rather undignified position of being an accidental intermediate host for this parasite, whose ultimate destiny is normally to live in the intestine of the dog.

It occurs widely throughout the world, with the exception of Scandinavia, USA, Central and most of South America and West Africa. The adult worms are less than 1 cm long and very many of them may live in the jejunum of a dog. The ova are normally accidentally ingested by herbivores, although humans can do so after handling the dog or by eating contaminated vegetables. The eggs hatch in the duodenum and the embryos pass through the mucosa into portal vein or lymphatics, coming to rest predominantly in liver and lung. Each embryo then develops into a cyst, from the delicate inner membrane of which brood capsules arise. The hydatid cyst grows slowly but after a decade may contain 1 L or more of fluid. The fluid contains a granular material consisting of brood capsules, scolices budded from within brood capsules and daughter cysts. This fluid is the agent by which the life cycle is completed, when the organ containing it is eaten by a dog or other scavenging carnivores such as foxes and wolves. A closely related species, *E. multilocularis*, has a very similar life cycle but the intermediate host is usually a rodent. It is prevalent particularly in northern Canada and the former USSR.

### Clinical features

Hydatid disease occurs most commonly in areas where sheep are reared, such as Australia, New Zealand, Wales, Greece, North Africa and the Middle East. There is usually a history of contact with dogs. Cysts may occur in any organ but liver, lung and muscle are most commonly involved, with kidney, bone and brain occasionally being affected. The lesions grow steadily and, though many cause no symptoms, may eventually come to the patient's attention because they rupture or become infected or because of pressure effects.

Pulmonary lesions are usually incidental radiological findings. They present as spherical lesions with well-defined edges and of uniform density. They are frequently multiple and bilateral [87]. Rupture is accompanied by expectoration of salty-tasting fluid and the radiograph may then show a fluid level in the lesion, sometimes with the membrane floating on the surface to give the 'water-lily' sign (Fig. 22.4). Liver cysts may be present also and may be palpable as fluctuant lesions on the surface of the organ. Calcification in the walls of cysts may be seen radiologically.

Hydatid disease commonly presents as a result of complications of the presence of cysts, which may become infected or may rupture causing hepatobiliary, hepatobronchial or bronchopulmonary fistulae or pneumothorax [87–89]. Occasionally, rupture may provoke anaphylaxis and this is a well-recognized, though rare, complication of surgery of the cysts [88,90]. Rupture is also liable to cause seeding of daughter cysts through the pleura or peritoneum. Whether associated with anaphylaxis, infection

**Fig. 22.4** Multiple hydatid cysts in lungs of patient from Greece. The large cyst in the right mid zone shows the 'water-lily' sign.

or spread of disease, these complications carry a high risk of mortality.

### Diagnosis and management

The condition is suspected clinically in people from sheep-farming areas in contact with dogs and who show appropriate radiological signs. Occasionally, after pulmonary cyst rupture, scolices may be seen in the sputum. The traditional Casoni skin test using hydatid fluid is insufficiently specific or sensitive as a reliable diagnostic tool, although latex agglutination and complement fixation tests are useful for detecting the presence of antibodies.

In many cases, the lung lesions are only diagnosed definitively at surgery. In general, in view of the very serious effects of complications, all such lesions should be removed, although it has been suggested that the relatively benign variant endemic in north-west Canada causes few complications and may resolve spontaneously [91]. Uncomplicated cysts may be removed easily without lung resection; an incision is made in the outer false capsule and the complete cyst is expelled through it when the anaesthetist inflates the lung [90]. Many cysts may be removed in this way without any loss of lung. If the cyst has ruptured into a bronchus or become infected, lobar or segmental resection is necessary. Hepatic cysts also require surgical treatment, and the surgery of hepatopul-

monary rupture is complex [89,90]. There has been much debate about sterilizing cysts prior to surgery. Some authorities aspirate some fluid and replace it with dilute iodine, formaldehyde or silver nitrate solution. Others argue that this increases the risk of rupture. The best guarantee of success is probably the experience of the surgeon.

Intrapleural rupture constitutes an emergency, requiring tube drainage, antianaphylactic measures sometimes, and urgent thoracotomy to remove pleura and affected lobe after irrigation of the pleural space with formaldehyde. In the case of cyst rupture, the antihelmintic alben-dazole should be used in conjunction with surgical measures; doses of 10 mg/kg daily for 3–4 weeks may be necessary. The role of antihelmintics is not clearly established but there is now much evidence that they are capable of sterilizing cysts and curing some, though they are not always effective [92–94]. There seems to be a strong case for their use in cyst rupture, perisurgically [95] and where surgery is thought to be too risky.

Measures to prevent endemic hydatid disease have been successful in some countries, notably Iceland, Tasmania and New Zealand. These involve educating farmers and others to prevent access of dogs to offal.

### Cysticercosis

Cysticercosis is not a pulmonary disease, although the

elongated, ovoid, calcified lesions may occasionally be seen in the chest wall muscles on radiographs. The disease is acquired when humans inadvertently become the intermediate host for *Taenia solium*, the pork tapeworm. This may occur when ova excreted in infected faeces are swallowed or, possibly, from development of ova in the stomach of an infected person when gravid segments are regurgitated from the small bowel. The cysts lodge in tissues and may present in subcutaneous tissue, muscle and brain particularly. Clinical effects arise from central nervous system involvement, epilepsy being the most frequent result. Apart from appropriate symptomatic treatment, surgical removal may be tried. Drug therapy directed against the larval worm is probably of little value.

## Arthropod parasites

The only arthropods that parasitize the lungs of humans are the tongue worms of the class Pentastomida, *Linguatula serrata* and *Armillifer* spp. [96]. They have no external appendages other than two pairs of hooks by the mouth and thus resemble worms, a resemblance made all the more close in some species by the presence of rings on their bodies. The adult parasite is up to 2 cm long and lives in the respiratory tract and nasopharynx of wild

mammals. Ova may be shed in sputum or faeces and picked up by reptiles (especially snakes) or other mammals; the larvae are not species specific. The eggs hatch in the gut and the larvae burrow through into the peritoneum and tissues, encysting in muscle and liver particularly. If the host is then eaten, the cysts hatch and the developing adult migrates to the lungs and nasopharynx.

Humans may be the intermediate or definitive host. If the cysts in raw meat are ingested, what is probably an anaphylactic reaction develops, with acute nasopharyngeal inflammation, vomiting, cough and wheeze, known in the Middle East as halzoun [97]. The adults are capable of developing and may reach the lung where they cause a granulomatous reaction that leads to fibrosis and calcification and where the organism is usually an incidental finding [98–100]. Infection with *Linguatula* has been reported in Europe and the Middle East, whereas *Armillifer* infections occur quite commonly in tropical areas. Infection can be avoided by not eating uncooked meat—raw snake meat in Africa and Malaysia is apparently an important source of infection! In general, no treatment is required except for anaphylactic reactions, when epinephrine (adrenaline) and hydrocortisone may be necessary.

# CHRONIC BRONCHITIS AND EMPHYSEMA

WILLIAM MACNEE

## Definitions and terminology

There is no universally accepted terminology or definition for the group of conditions characterized by airways obstruction that is incompletely reversible [1]. There are several problems that have to be considered. The first results from the use of the term 'chronic obstructive pulmonary disease' (COPD), which is considered inaccurate since this is not truly a disease but a group of diseases. The second relates to the British preference for the terms 'chronic bronchitis' and 'emphysema', which although describing two conditions with an apparently more precise clinical or pathological definition, lack any reference to airways obstruction in their definitions. The third problem, which is the most difficult to resolve, is the concern over differentiating this condition from asthma, which the terms 'chronic bronchitis' and 'emphysema' seem to do whereas this is not the case for COPD. In all the recent consensus statements from scientific societies, COPD is the term used and is considered as a separate condition from asthma [2–4]. This latter problem is compounded by the fact that the persistent airways obstruction in older chronic asthmatics is often difficult or even impossible to differentiate from that in COPD, although a history of heavy cigarette smoking, evidence of emphysema by imaging techniques, decreased diffusing capacity for carbon monoxide and chronic hypoxaemia favour a diagnosis of COPD [3].

*Chronic bronchitis* is defined as the presence of a chronic productive cough on most days for 3 months, in each of two consecutive years, in a patient in whom other causes of chronic cough have been excluded [5]. *Emphysema* is defined as abnormal, permanent enlargement of the distal airspaces, distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis [6]. Thus chronic bronchitis is defined in clinical terms, whereas emphysema is defined pathologically.

A group of synonyms have arisen, which in the UK include chronic obstructive bronchitis or chronic bronchitis with airways obstruction; in the USA, COPD, chronic

obstructive airways disease (COAD) and chronic obstructive lung disease are favoured. However, the term 'chronic bronchitis and emphysema' has often been used loosely to define a patient with chronic cough and associated airflow obstruction, although airflow obstruction does not appear in the definition. The most widely used term is COPD, which has been accepted in the British Thoracic Society (BTS) guidelines on the management of this condition [4] and is the title of a major British textbook on the subject [7].

Chronic bronchitis has been classified into three forms: simple bronchitis, defined as hypersecretion of mucus; chronic or recurrent mucopurulent bronchitis in the presence of persistent or intermittent mucopurulent sputum; and chronic obstructive bronchitis when chronic sputum production is associated with airflow obstruction. The use of the term 'chronic obstructive bronchitis' arose from the 'British hypothesis' that persistent recurrent infection, and thus chronic sputum production, resulted in damage to the airways and hence airways obstruction. However, the term has never found favour outside the UK.

As with chronic bronchitis, the definition of emphysema does not require the presence of airflow obstruction. Many studies in the past have attempted to predict the presence and extent of emphysema in life. However, the use of respiratory function tests and the assessment of pulmonary emphysema by plain chest radiography is imprecise [8]. Furthermore, attempts to determine the relative contribution made by airway abnormalities or distal air-space enlargement to the airways obstruction in an individual patient with COPD has proved elusive. Thus in the UK, in clinical practice the terms 'chronic bronchitis and emphysema' were used to describe patients, current or ex-smokers, who did or did not produce sputum chronically but who had persistent breathlessness and chronic airways obstruction. In contrast, in the USA in the early 1960s the term COPD was introduced to describe patients with largely irreversible airways obstruction due to a combination of airways disease and emphysema, without defining the contribution of these conditions to the airways obstruction. However, the wheel has now come

full circle since the BTS has now adopted the term COPD and produced guidelines for the treatment of this condition [4].

The guidelines published by the American Thoracic Society (ATS) define COPD as 'a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway reactivity, and may be partially reversible' [2]. The European Respiratory Society (ERS) has adopted a similar definition: 'a disorder characterized by reduced maximum expiratory flow and slow forced emptying of the lungs; features which do not change markedly over several months' [3]. The definition adopted by the BTS is similar: 'a slowly progressive disorder characterized by airways obstruction (reduced  $FEV_1$  and  $FEV_1/VC$  ratio), which does not change markedly over several months. Most of the lung function impairment is fixed, although some reversibility can be produced by bronchodilator (or other) therapy' [4].

The BTS guidelines suggest that a diagnosis in clinical practice is usually associated with:

- 1 a history of chronic progressive symptoms (cough, wheeze and/or breathlessness), with little variation;
  - 2 usually a cigarette smoking history of greater than 20 pack-years (1 pack-year is equivalent to smoking 20 cigarettes a day for 1 year);
  - 3 objective evidence of airways obstruction, ideally by spirometry, that does not return to normal with treatment.
- A number of specific causes of chronic airways obstruction are not included in the term COPD, such as cystic fibrosis, bronchiectasis and bronchiolitis obliterans (e.g. associated with lung transplantation and chemical inhalation). The differentiation of COPD from asthma remains a problem, particularly as a large proportion of patients with COPD show some improvement in airflow obstruction with bronchodilators. However, in clinical practice the definition is less important than assessing whether patients show reversibility of their airways obstruction, since this influences their management.

Snider has popularized the use of a Venn diagram that shows the relationships between chronic bronchitis, emphysema and asthma (Fig. 23.1).

## Epidemiology

### Prevalence

Hypersecretion of mucus is a symptom that has been extensively studied in general population surveys over the last 40 years. In these studies, usually in middle-aged men, the prevalence of chronic cough, or chronic cough and the production of sputum, ranges between 15 and 53%, with a lower prevalence of 8–22% in women, being more prevalent in urban than rural areas [9,10]. The most

**Fig. 23.1** A non-proportional Venn diagram describing the relationship between patients with chronic bronchitis, emphysema and asthma. The broken line rectangle includes all patients with airflow obstruction. Patients in subsets 1 and 2 have clinical or radiological features of chronic bronchitis or emphysema but do not have airflow obstruction and thus have a normal forced expiratory volume in 1 s ( $FEV_1$ ) and  $FEV_1$ /forced vital capacity ratio. These patients are not classified as having chronic obstructive pulmonary disease (COPD). Patients in subsets 6–8 have partially reversible airflow obstruction. Subsets 3, 4 and 5 have no significant reversibility and patients in subset 8 have features of all three disorders. Those in subset 9 have completely reversible airflow obstruction and thus have asthma. Those in subset 10 have airflow obstruction due to specific pathology such as cystic fibrosis, bronchiectasis or obliterative bronchiolitis. Patients with COPD are those patients within the thick shaded band. (After Snider [1].)

recent study in the late 1980s showed a decline in the prevalence of chronic cough and phlegm in middle-aged men to 15–20%, with little change in women [10]. This compares with a prevalence of approximately 4% in these symptoms in people who have never smoked. Smoking low-tar cigarettes results in less cough and phlegm than smoking high-tar cigarettes [11].

Prevalence studies of COPD are normally based on values of percentage predicted forced expiratory volume in 1 s ( $FEV_1$ ), which defines individuals with and without airways obstruction. In the UK in a survey in 1987 of a representative sample of 2484 men and 3063 women in the age range 18–64 years, 10% of men and 11% of women had an  $FEV_1$  greater than 2 standard deviations (SD) below their predicted values, the numbers increasing with age, particularly in smokers [12]. In current smokers in the age range 40–65, 18% of men had an  $FEV_1$  greater than 2 SD below normal and 14% of women compared with 7% and 6% of non-smokers respectively.

Studies from the USA, which used a cut-off  $FEV_1$  of less than 65% of the predicted value, provide similar figures, with prevalence falling in men from 8% in the 1960s to 6% in the late 1970s, whereas the 3% prevalence in women did not change over this period [13]. National surveys of con-

Diagnosis	Age	Men (per 1000)			Women (per 1000)		
		1955–56	1970–71	1981–82	1955–56	1970–71	1981–82
Chronic bronchitis	45–64	32.7	29.6	12.3	12.9	12.0	6.7
	65–74		73.8	37.9		23.5	13.6
Emphysema and COPD	45–64	3.1	3.4	6.5	0.2	0.5	3.0
	65–74		11.1	26.2		1.5	7.8

**Table 23.1** Annual general practitioner consultations for chronic respiratory disease in the UK 1955–56, 1970–71 and 1981–82. (From Strachan [14].)

sultations in British general practices have shown the changes in prevalence of clinically diagnosed chronic bronchitis, emphysema and COPD over the last 40 years (Table 23.1). These data show a modest decline in the number of middle-aged men consulting their GP with symptoms suggestive of COPD and a slight increase among middle-aged women. These trends are confounded by changes over the years in the application of the diagnostic labels for this condition, particularly the overlap between COPD and asthma [15].

**Mortality**

There are large international variations in the death rate for bronchitis, which cannot be entirely explained by differences in diagnostic patterns and labels or by differences in smoking habits [16]. Certified cause of death can be misleading, particularly where pneumonia is often used as the underlying cause of death. Furthermore, chronic bronchitis

and emphysema or COPD is often a contributory factor to the cause of death. It is likely therefore that the use of death rates from certification of these conditions underestimates the true mortality due to COPD. Most of the mortality from this condition occurs in the over-65 age group. The highest death rates for COPD among the developed countries occur in the UK, eastern Europe and Australia, with low rates in southern Europe, Scandinavia and Japan [16]. In 1984 British death rates for COPD for both sexes were exceeded only by Romania. As mentioned above, international comparisons of mortality are complicated by the use of different diagnostic labels. In the UK, chronic bronchitis (International Classification of Disease (ICD)-8 and ICD-9, 491) was the common certification of such deaths until a separate code for chronic airways obstruction not elsewhere classified was introduced in 1978 (ICD-8,591; ICD-9, 496), thereafter termed COAD and which has been used increasingly (Fig. 23.2).

Within the UK, age-adjusted death rates from chronic

**Fig. 23.2** Age-standardized mortality rates in Europe 1988–91 for chronic obstructive pulmonary disease (COPD). ICD-9, 490–496 describes COPD and similar conditions. Shaded bars to the left indicate mortality rates in males; White bars to the right indicate mortality rates in females. (From Siafakas *et al.* [3] with permission.)

respiratory diseases vary by a factor of more than five in men and more than 10 in women in different geographical locations [17]. Mortality rates tend to be higher in urban areas than rural areas and there is a trend for higher rates in South Wales and Scotland independent of urbanization. Mortality from chronic respiratory disease (ICD-9, 490–493 and 496) in males aged 55–84 years has been falling, except in the oldest age group over 75 years of age. In the USA, similar trends have been recorded in males, whereas in women the mortality is one-third that of males; the decline in mortality, which was recorded until 1975, has since then shown a slight increase in women over the age of 65 years [18]. These trends presumably relate to the differences in the time of the peak prevalence of cigarette smoking in men and women, which occurred later in women. In England and Wales in 1992 there were 3873 deaths certified as due to chronic bronchitis, 1946 due to emphysema, 1791 due to asthma and 19963 due to COAD [17]. Together these accounted for 6.4% of all male deaths and 3.9% of all deaths in females [17]. Similar percentages of the total death rates occurred for COPD in Scotland.

### Social class

The association between respiratory diseases and social class in the UK is well recognized. Data from the 1981 census showed that standardized mortality ratios for chronic bronchitis, emphysema and asthma were three to six times greater in social classes 4 and 5 compared with social classes 1 and 2 [19]. These social class trends in men are also apparent in women (classified by their husbands' occupation), suggesting that occupational exposure does not explain these socioeconomic differences. In addition, smoking only partly explains these trends in mortality related to socioeconomic status, since population surveys have shown associations between spirometry or decline in spirometry and socioeconomic status that are independent of current smoking habit [12].

There is evidence, from a national follow-up to adult life of a cohort born in 1946, of a strong association between social deprivation in childhood, particularly domestic overcrowding, and ventilatory capacity and cough, suggesting that conditions in early life influence the development of chronic respiratory disease in adulthood [20].

### Morbidity and use of health resources

COPD places an enormous burden on healthcare resources [10]. Table 23.2 gives an estimate of the annual workload in primary and secondary care attributable to COPD and its associated conditions in an average UK health district with a population of 250 000. It has been calculated that chronic bronchitis and emphysema, COPD and asthma account for 24.4 million working days lost per year, which represents 9% of all certified sickness absence among men; the equivalent figures for women are 3.1 million working days lost, 3.5% of the total certified sickness absence [21]. Respiratory diseases in the UK rank as the third most common cause of days of certified incapacity, COPD accounting for 56% of these days in males and 24% in females [22].

### Aetiology

#### Chronic hypersecretion of mucus and persistent airflow obstruction

The landmark studies of Fletcher and colleagues [23] indicate that although both chronic hypersecretion of mucus and progressive, persistent airflow obstruction occur in cigarette smokers, their influence on survival is quite distinct. These features arise from abnormalities in different lung sites. The persistent cough and sputum production results from bronchial gland enlargement in the proximal conducting airways and improves following cessation of cigarette smoking, whereas the persistent airflow obstruction arises from damage to the peripheral airways and airspaces and is persistent after the cessation of cigarette smoking.

Population studies of respiratory symptoms show a much higher prevalence of cough and sputum among smokers compared with non-smokers. Indeed the presence of chronic bronchitis has been almost confined to cigarette smokers. For example, a survey in urban and rural populations in the UK found a history of chronic bronchitis in 17.6% of males aged 55–64 who were heavy smokers, in 0.9% of light smokers, in 4.4% of ex-smokers and in no non-smokers [24].

Pipe and cigar smokers have a much lower prevalence of chronic bronchitis and less impairment of respiratory

**Table 23.2** Estimated annual health service workload due to chronic respiratory disease in an average UK health district serving 250 000 persons. (Modified from Anderson *et al.* [10].)

	Hospital admissions	Inpatient bed-days	General practice consultations
Chronic bronchitis	100	1500	4400
Emphysema and COPD	240	3300	2700
Asthma	410	1800	11900
Total	750	6600	19000

function, despite a similar capacity for cigarette smoke and cigar smoke to cause bronchial reactivity [25]. This may reflect lower rates of smoke inhalation in pipe and cigar smokers. Filter-tip cigarettes also have less propensity to incite cough and sputum production [26].

Fletcher and colleagues [23] demonstrated that around 20% of male cigarette smokers aged 50 had an  $FEV_1$  within 2 SD of their normal value. If a smoker stops smoking, then in 90% the sputum production ceases [27]. These studies emphasized the dissociation between chronic persistent cough and phlegm and airflow obstruction. In an 8-year prospective study of working men in West London, Peto and coworkers [28] were unable to demonstrate an independent correlation between the degree of hypersecretion of mucus and an accelerated decline in  $FEV_1$ , after the data were adjusted to account for age, smoking and the absolute value of the  $FEV_1$ . There was also no association between hypersecretion of mucus and mortality. By contrast, morbidity and mortality in COPD are strongly related to the development of low  $FEV_1$  (Fig. 23.3). Recent data from Denmark suggest that the concept of a lack of association between sputum production and decline in  $FEV_1$  may have to be revised [29].

**Risk factors**

Cigarette smoking is clearly the single most important identifiable aetiological factor in COPD. However, only 10–20% of smokers develop clinically significant COPD, while approximately half never develop a clinically significant physiological deficit [30,31]. The factors that identify the cigarette smoker susceptible to the development of progressive airflow obstruction are still a matter of much debate and research. Since there is a strong association between a low  $FEV_1$  and both morbidity and mortality in COPD, risk factors are usually assessed by studying the relationship with mortality or with accelerated annual decline in  $FEV_1$ .

**Cigarette smoking**

The evidence that tobacco smoking is the most important aetiological factor in COPD is overwhelming [32,33]. The greater the total tobacco exposure, the greater the risk of developing COPD [30] (Fig. 23.4). Pipe and cigar smokers have higher morbidity and mortality rates for COPD than non-smokers, although their rates are lower than cigarette smokers [30]. Although it is generally regarded as the dominant risk factor, cigarette smoking is not a prerequisite in all definitions of COPD [2,3] since COPD can occur in non-smokers, such as patients with  $\alpha_1$ -antitrypsin deficiency [34]. However, the BTS guidelines suggest that most patients with COPD have at least a 20 pack-year smoking history [4].

On average, cigarette smokers have a high annual rate of decline in  $FEV_1$  of about 50 mL, which is nearly double

**Fig. 23.3** Risk ratios for death from chronic obstructive pulmonary disease: (a) according to initial value of height-corrected forced expiratory volume in 1 s ( $FEV_1/H^3$ , where  $H$  is height in metres) at survey 20–25 years previously (bars indicate standard errors); (b) according to presence of phlegm after standardization for  $FEV_1/H^3$ . (Modified from Peto *et al.* [28] with permission.)

the average value of 30 mL annually present in non-smokers. However, there is considerable variation in the decline in  $FEV_1$ , with some smokers showing very rapid rates of decline. In non-smokers the  $FEV_1$  begins to decline

Fig. 23.4 Death rates due to bronchitis in British male doctors per 100 000 according to smoking habit. (Data from Doll & Peto [38].)

at 30–35 years of age, and this may occur earlier in smokers [35]. The decline in  $FEV_1$  may be faster early in the natural history of the disease before COPD is established [36]. Stopping cigarette smoking does not produce a substantial improvement in  $FEV_1$  but the subsequent rate of decline is decreased [23,37]. This was clearly shown in the Lung Health Study where the decline in  $FEV_1$  slowed in those smokers who quit smoking [37] (Fig. 23.5). There is a less striking relationship between annual decline in  $FEV_1$  and the reported daily number of cigarettes smoked, since there is wide variation in the annual rate of decline among smokers with the same smoking history [38]. In broad terms, however, mortality from COPD is twofold greater in those who smoke more than 25 cigarettes a day compared with those smoking fewer than 15 cigarettes a day.

There are other confounding factors that complicate the relationship between numbers of cigarettes smoked and rate of decline in  $FEV_1$ . These are the extent to which cigarette smoke is inhaled and the tar, nicotine and other constituents [11]. Although a reduction in the tar content of the cigarettes smoked reduces hypersecretion of mucus [37], it has a small, if any, effect on the progression of airflow obstruction and any improvement may be outweighed by a change in the pattern of the number of cigarettes smoked [35].

The most important evidence associating smoking and mortality from bronchitis is that from the studies of Doll and Peto [38]. In a study mainly determining the aetiology of lung cancer, 40 000 medical practitioners in the UK recorded their smoking habits. The cause of death was determined later in those who died during the follow-up period. In this study the death rate for chronic bronchitis

Fig. 23.5 Mean forced expiratory volume in 1 s ( $FEV_1$ ) after bronchodilator in subjects in the Lung Health Study who were sustained quitters and those who continued to smoke. (From Anthonisen [37] with permission.)

was significantly higher in cigarette smokers than in non-smokers and increased with the amount smoked. In those who stopped smoking, the mortality 10 years on was well below that for all smokers. In male doctors aged 35–64, mortality from chronic bronchitis between 1953–67 and 1971–75 fell by 24% compared with a fall of only 4% in other men in the UK of the same age. This difference was attributed to the decrease in smoking in doctors compared with an overall increase in smoking in the general population [39]. Similar results to the UK study have been published in other population studies in the USA [40] and in a 20-year follow-up study of female British doctors [41].

The effects of smoking cessation on mortality have been less clear. Randomized controlled trials fail to demonstrate a unequivocal benefit in terms of respiratory mortality from stopping smoking [36,42]. In one study on smoking habits, fewer deaths from emphysema occurred in smokers of lower tar cigarettes than in smokers of medium- or high-tar cigarettes [43].

### Passive smoking

In view of the weak but statistically significant association between lung cancer in people who have never smoked and environmental tobacco smoke, or 'second-hand smoke' exposure [44], a relationship between passive smoking and the development of chronic airflow obstruction might also be expected. This relationship has been examined using case-control studies [45,46] and a cohort study [46]. These studies show a trend towards an increased relative risk from passive smoking, similar to that of lung cancer but not powerful enough to demonstrate statistical significance.

Passive smoking does not appear to have a convincing

effect on pulmonary function in middle-aged adults [48]. However, in a study of young adult non-smokers, cumulative lifetime exposure to environmental tobacco smoke during childhood was associated with significantly lower peak levels of FEV<sub>1</sub> in adulthood [49]. Maternal smoking in pregnancy is associated with low birthweight [50] and smoking by either parent is associated with an increased incidence of respiratory illnesses in the first 3 years of life [48]. Studies of the relationship between parental smoking and lung growth in childhood have produced inconsistent findings [51,52].

Increased airways resistance occurs after smoking only one cigarette [53]. This can be blocked by atropine, suggesting that it could be an irritant receptor reflex-induced phenomenon [54].

### Air pollution

Interest in air pollution as a risk factor in chronic respiratory disease was stimulated by the London smog of December 1952 [55], to which 4000 excess deaths due to cardiorespiratory disease were attributed among the elderly, particularly those with poor cardiorespiratory reserve. Several studies in the 1950s, 1960s and early 1970s produced evidence incriminating air pollution as an aetiological factor in COPD, including:

- 1 the association, in the UK, between increasing mortality and prevalence of COPD and increasing urbanization [56,57];
- 2 the close association between atmospheric pollution and mortality from COPD both geographically and temporarily [58];
- 3 the demonstration that post office employees in foggy areas showed a higher rate of invalidity than those working in less foggy areas [59];
- 4 the increase in reported symptoms of chronic bronchitis in areas of increased air pollution [60];
- 5 a higher prevalence of emphysema in autopsy studies in areas with greater pollution [60].

The introduction of the Clean Air Acts (1956, 1965) led to a reduction in smoke and sulphur dioxide levels during the 1960s, which produced less discernible peaks of pollution related to morbidity and mortality compared with the 1950s [60]. In 1992, a World Health Organization (WHO) expert committee on air pollution [61] concluded that high concentrations of sulphur dioxide (150 µg/m<sup>3</sup>) or similar concentrations of particulate air pollution, measured as black smoke, were associated with increased morbidity in terms of symptoms and hospital admissions in adult patients with COPD. Levels of sulphur dioxide or black smoke in excess of 500 µg/m<sup>3</sup> would be expected to increase mortality among the elderly and those with poor cardiopulmonary reserve. Thus there was a belief that current air pollution, generally at lower levels even in urban areas in the UK, had no influence on the morbidity

and mortality from COPD. More recent studies, particularly from the USA, have cast doubt on this conclusion and indicate an association between respiratory symptoms in patients with airways disease, clinician consultations or hospital admissions with airways diseases and levels of particulate air pollution (black smoke) below 100 µg/m<sup>3</sup>, levels currently experienced in many urban areas of the UK [62]. Furthermore, levels of particulate air pollution are associated with deaths from all causes, particularly cardiorespiratory deaths [63].

There appears to be no threshold for the association between particulate air pollution and mortality. It is interesting that the last of the great London smogs, which occurred in the winter of 1962–63, produced an increased morbidity and mortality from bronchitis but to a level less than in 1952. The sulphur dioxide concentrations were similar in both years but the smoke concentrations were much lower in 1962 and so was the associated respiratory mortality [64]. This evidence, and the fact that the association between particulate air pollution and respiratory morbidity and mortality was demonstrated in such diverse locations as Utah (where the particulate air pollution is derived mainly from a steel mill) and Los Angeles (where it is largely motor vehicle exhaust), led to the suggestion that the composition of the particulate pollution was not the critical factor [63].

One hypothesis is that the fine particles in air pollution, with an aerodynamic diameter of less than 10 µm (PM<sub>10</sub>), or the ultrafine particles, which have a diameter in the nanometer range, may have properties related to size, acidity or ability to generate oxidants that increases the permeability of the airway epithelium [65]. This may contribute to airway inflammation, which may lead to a pro-coagulant state and hence to the increased cardiovascular mortality that has been shown to be associated with increased levels of environmental particulate air pollution [63].

Although there have been associations between exacerbations of airways diseases and photochemical air pollutants, such as nitrogen dioxide and ozone, this association has been largely confined to patients with asthma [66]. There are no studies showing an association between ozone and deaths from respiratory diseases [66]. There is an association between environmental nitrogen dioxide levels and short-term effects on symptoms or pulmonary function, both from laboratory and community-based studies of patients with chronic respiratory diseases [67]. There are a few longitudinal studies on the effects of air pollution on the decline in lung function. However, a study of a population born in 1946, who would have been exposed to high levels of smoke and sulphur dioxide in childhood, was unable to demonstrate a major effect of exposure to air pollution in childhood and the later development of chronic bronchitis on measurements of peak expiratory flow rate in this population's fourth decade

[68]. By contrast, in a study from Sheffield, where there has been a substantial decrease in the formerly very high levels of air pollutants, patients in the later less-polluted period had less productive cough, fewer winter illnesses, less severe breathlessness and only one-third the rate of decline of FEV<sub>1</sub> compared with those studied in the earlier highly polluted period [69].

### Protease inhibitor deficiency

$\alpha_1$ -Antitrypsin ( $\alpha_1$ -AT) or  $\alpha_1$ -protease inhibitor ( $\alpha_1$ -Pi) is a polymorphic glycoprotein responsible for the majority of the antiprotease activity in the serum [70]. Laurell and Eriksson [71] in 1963 were the first to describe the association between  $\alpha_1$ -AT deficiency and the development of early-onset emphysema. Their initial discovery of the absence of the  $\alpha_1$  band in a number of sera on routine electrophoresis led to the observation that three of the original five subjects with this abnormality had severe early-onset emphysema. Later the clinical, biochemical and genetic features were described in detail by Eriksson, showing that the abnormality was transmitted as an autosomal recessive gene [72].

Since the discovery of the deficiency, over 75 biochemical variants have been described. The commonly recognized alleles are designated by capital letters relating to their electrophoretic properties, which gave rise to the phase inhibitor or Pi nomenclature, e.g. PiZ. The commonest allele in all populations is PiM and the most common genotype is PiMM, which occurs in around 86% of the UK population. PiMZ and PiMS are the next two most common genotypes and are associated with  $\alpha_1$ -Pi levels of 50–75% of the mean levels of PiMM subjects, as is the much less common PiSS type. The homozygous PiZZ deficiency, in which serum levels are 10–20% of the average normal value, is the strongest genetic risk factor for the development of emphysema and the associated airflow obstruction and forms the basis of the proteolytic theory of the pathogenesis of emphysema [73]. The most important other type is PiSZ, where basal levels are 35–50% of normal values. A few rare variants that result in complete functional absence of  $\alpha_1$ -Pi account for the remainder of the severely deficient patients.

In the USA, studies in which adult blood donors were screened identified a 1 in 2700 prevalence of PiZZ subjects, of whom most had normal spirometry [74]. It has been calculated that about 1 in 5000 children in the UK are born with the homozygous deficiency (PiZZ) [75]. However, the number of identified subjects with disease is much less than predicted from the known prevalence of the deficiency [76]. Therefore it is by no means inevitable that all individuals with a homozygous deficiency develop respiratory disease. Indeed a few identified PiZZ individuals live beyond their sixth decade and escape the development of progressive airways obstruction [77].

The incidence of  $\alpha_1$ -Pi deficiency in a population study of patients presenting with COPD was 1–2% [78] but rises to greater than 50% in patients with severe disease who are less than 40 years of age [79]. Prospective follow-up of PiZZ subjects has shown a greatly accelerated decline in FEV<sub>1</sub>, but with large variations between individuals [80]. There is a clear interaction with cigarette smoking, although this cannot entirely account for the variation in decline in FEV<sub>1</sub> observed among individuals. Life expectancy of subjects with  $\alpha_1$ -Pi deficiency is significantly reduced, especially if they smoke [76].

The onset of dyspnoea and death occur at a younger age in smokers with  $\alpha_1$ -Pi deficiency. In a study of deficient subjects in New Zealand, dyspnoea began on average at age 32 years in smokers compared with 51 years in non-smokers. The mean age at death in this group was 48 years for smokers and 67 years for non-smokers with PiZZ [81].

### Occupation

It is generally accepted that there is a causal link between occupational dust exposure and the development of mucous hypersecretion [82]. However, the relationship, particularly in coal-miners, between the development of airways obstruction and dust exposure at work has been controversial [83]. Cigarette smoke has been a confounding factor since the prevalence of smoking remains disproportionately high in many workers exposed to dust at work. The problem is compounded by the fact that only 20% of smokers develop COPD, that there may be an interaction between cigarette smoking and dust exposure, and that workers in dusty occupations often live in areas of high air pollution.

Longitudinal studies by Becklake [82] on workforces exposed to dusts or gases only, or a combination of the two, show an association with dust exposure resulting in a more rapid decline in FEV<sub>1</sub>. Cross-sectional studies in the general population of single measurements of ventilatory function and symptoms by questionnaire have limitations but show a relationship between impairment of ventilatory function and exposure to dusts [84]. Longitudinal studies of British coal-miners indicate a relationship between the exposure to dust and the development of a small excess longitudinal decline in FEV<sub>1</sub> [85–87] and increased mortality [88]. The risk of disabling loss of ventilatory function (defined as a mean loss in FEV<sub>1</sub> of 942 mL, which occurred in the miners with disabling symptoms) is less than 5% among non-smoking miners with low cumulative exposures to coal dust (<100 mg/h/m<sup>3</sup>), but increases exponentially to 20% in those with heavy cumulative exposures (500 mg/h/m<sup>3</sup>). Smoking also appears to enhance the effect of increasing dust exposure levels and the risk of developing COPD.

The accumulating evidence for an association between

coal-dust exposure and the development of COPD led recently in the UK to the establishment of COPD as a disease considered for compensation in miners. The criteria for compensation are work underground for at least 20 years and a reduction in FEV<sub>1</sub> of at least 1 L from the predicted value [83].

A small but significant effect of exposure to welding fumes and the development of COPD was shown in a study of shipyard workers [89]. Workers exposed to cadmium can develop emphysema and hence COPD [90]. Cadmium is also a trace component of cigarette smoke. Since cumulative exposures to cadmium through smoking are not likely to approach those achieved occupationally, smoking-induced emphysema cannot be attributed to cadmium.

### Chronic bronchopulmonary infection

In the 1950s it seemed reasonable to hypothesize that since patients with chronic bronchitis often had bacteria in their sputum [91], recurrent bronchopulmonary infections would result in damage to the airways and progressive airways obstruction. Thus a 'British hypothesis' was developed which stated that smokers who had chronic hypersecretion of mucus were at risk of bronchopulmonary infections, which caused airway damage and progressive airways obstruction. However, studies in the 1960s and 1970s in men with chronic bronchitis demonstrated that prophylactic antibiotics to prevent recurrent infective exacerbations did not slow the decline in lung function [92,93]. Furthermore, Fletcher and colleagues [23,28], in their 8-year prospective study of working men in West London, showed that neither hypersecretion of mucus nor bronchial infection caused a more rapid decline in FEV<sub>1</sub> after adjusting for age, smoking and the level of FEV<sub>1</sub>. However, acute bronchopulmonary infection did show an association with an acute decline in lung function, which may persist for several weeks but which usually recovered completely.

Many studies from both western Europe and North America have shown a relationship between a low FEV<sub>1</sub> and an increased risk of death from COPD [94,95]. Although some studies have shown a low risk of death from COPD in relation to hypersecretion of mucus [96,97], others have found more important risk-ratios of up to three- to four-fold [29,94], though still less important than the effect of FEV<sub>1</sub> [28].

Although studies in the general population and in smokers failed to demonstrate a strong association between the annual rate of decline in FEV<sub>1</sub> and recurrent bronchopulmonary infection, these studies have been in smokers with only mild impairment of lung function. Therefore the results can only be applied to this group and not to the group of patients with established and more severe COPD, in whom recurrent bronchopulmonary

infections are more frequent. Indeed, one study in Salt Lake City did find an association between lower respiratory tract infection and an accelerated decline in FEV<sub>1</sub>, but in a group who already had established COPD [97]. Furthermore, in a large community study in Copenhagen, Lange and coworkers [29] found that hypersecretion of mucus was associated with a fourfold greater relative risk of death from COPD if the FEV<sub>1</sub> was 40% of predicted compared with a group of individuals whose FEV<sub>1</sub> was 80% of predicted.

Intraluminal airspace inflammation is a characteristic of chronic bronchitis [98–101]. Peripheral blood white cell count, which is 30% higher in smokers than non-smokers, has an inverse relationship with FEV<sub>1</sub> [102,103]. The relationship between peripheral leucocyte cell count and FEV<sub>1</sub> is perhaps more complex than the association of respiratory infection, since peripheral white cell count relates not only to the release of neutrophils from the bone marrow but also to the sequestration of neutrophils in the pulmonary microcirculation [104].

Chest illness in childhood appears to have an association with chronic respiratory morbidity and impaired respiratory function in adulthood [105]. It remains unclear whether these episodes of infection in early life cause lung damage or reflect an underlying susceptibility to lower respiratory infection [106]. There is also controversy over the relationship between childhood or infant respiratory infection and ventilatory impairment in later life. A study of health visitor records of illnesses in early childhood suggested that illnesses diagnosed as whooping cough, bronchiolitis or pneumonia in the first year of life were associated with a significant reduction in FEV<sub>1</sub> measured in the first decade [107]. In contrast, the same illnesses in children aged 1–4 years were not associated with significant defects in lung function.

However, studies of a cohort of children born in 1946 reported that cough and sputum production between the ages of 20 and 36 years were more commonly reported in those with a history of chest illness in childhood [108,109]. In contrast, respiratory illnesses below the age of 2 years had no effect on peak expiratory flow rate at age 36 years [68]. One of the problems with these studies is the confusion of diagnosing asthma in those who might previously have been diagnosed as having bronchitis, which appears to have a close association with chronic respiratory problems in adulthood [110]. Indeed, it seems that those children who do not grow out of their asthma are at increased risk of chronic cough and sputum production in their early twenties [111].

### Growth and nutrition

Several recent studies have suggested that nutrition may affect both the growth and decline in ventilatory function. In a study of men born in Hertfordshire between 1911 and

1930, mortality from chronic respiratory diseases (ICD-9, 491–493 and 496) correlated inversely with birthweight and weight at 1 year of age [107]. Since a similar association did not occur with lung cancer, it was suggested that smoking is unlikely to be a confounding factor. Thus, impaired growth *in utero* may be a risk factor for the development of chronic respiratory diseases.

The association between childhood respiratory illness and ventilatory impairment in adulthood is probably multifactorial. Several factors, such as low economic status, greater exposure to passive smoking, poor diet and housing and residence in areas of high pollution, may contribute to this finding. One study has shown that in British adults there is a correlation between consumption of fresh fruit in the diet and ventilatory function [112], a relationship that held in both smokers and people who never smoked. Dietary factors, particularly a low intake of vitamin C and low plasma levels of ascorbic acid, were related to a diagnosis of bronchitis in the US National Health and Nutrition Examination Survey [113]. A relationship between heavy alcohol intake and a risk of impaired ventilatory function has been shown in one study [114].

#### Atopy and airway hyperresponsiveness

In the 1960s Dutch workers proposed that smokers with chronic, largely irreversible airways obstruction and asthmatics shared a common constitutional predisposition to allergy, airway hyperresponsiveness and eosinophilia [115]. This proposal named the 'Dutch hypothesis' by Fletcher and colleagues was contrary to Fletcher's own data, which failed to find a relationship between evidence of allergy or increased airway responsiveness to histamine and accelerated annual decline in FEV<sub>1</sub> in cigarette smokers [23]. Numerous studies have shown that smokers tend to have higher levels of IgE and higher eosinophil counts than non-smokers; however, the levels are not as high as those seen in asthmatics [116,117]. Studies in middle-aged smokers with a degree of impairment of lung function show a positive correlation between accelerated decline in FEV<sub>1</sub> and increased airway responsiveness to either methacholine or histamine [118,119]. However, atopic status, as defined by positive skin tests, does not differ between smokers and people who have never smoked [116,117,119].

There are several important differences between the airway hyperresponsiveness (AHR) in smokers, patients with COPD and patients with asthma. Cross-sectional studies have shown that AHR occurs more commonly in middle-aged than young non-atopic smokers [120]. Whereas in asthma AHR is present in those with normal baseline respiratory function, in smokers there is a strong relationship between baseline FEV<sub>1</sub> and AHR [121]. The relationship between AHR and diurnal variation in peak

flow is stronger in asthmatics than in smokers and the relationship between AHR and eosinophil count is present in asthmatics but not in smokers [115]. The bronchial hyperreactivity in asthmatics is more intense than in patients with COPD [122] and, as with normal subjects, patients with COPD show a plateau in airway narrowing as the dose of inhaled methacholine is increased [123,124], which does not occur in asthmatic subjects [123]. There are also differences in the short-term effects of drugs on AHR in smokers and patients with asthma. The  $\beta$ -adrenoreceptor agonists have a much larger short-term effect on attenuating AHR to histamine or methacholine than antimuscarinic drugs. This is true in both asthmatics and smokers with mild airflow obstruction [125]. This contrasts with clinical studies which suggest that antimuscarinic drugs may have more important effects and thus be more useful in smoking-related COPD [126]. Short-term studies of non-steroidal anti-inflammatory drugs have shown no effect on AHR in smokers [127]. However, smokers and asthmatics differ in the response of their AHR to treatment with corticosteroids, which given over 2–3 months effectively attenuates AHR in asthma but is ineffective in smokers with mild airways obstruction [128]. These studies suggest, but do not prove, that AHR in smokers may be acquired rather than constitutional. There are several possible mechanisms for the increased AHR in smokers with COPD [129]:

- 1 geometric factors related to an increased thickening of airway walls, producing a narrowed airway, result in a proportionally greater rise in resistance in a narrowed airway for a given shortening of airway smooth muscle;
- 2 more central deposition of inhaled aerosols as a result of airways obstruction;
- 3 loss of airway wall support as a result of loss of alveolar walls in emphysema;
- 4 increased airway epithelial permeability resulting in airway wall oedema.

One structure-function study has shown that the degree of bronchiolar inflammation is related to the hyperresponsiveness in cigarette smokers [130]. However, the infiltration of eosinophils into the airways of asthmatic subjects is much more prominent than in non-asthmatic smokers [100]. There is evidence that non-asthmatic smokers display several features of allergy. They certainly have raised levels of total serum IgE and higher blood eosinophil counts compared with healthy people who have never smoked [117,131]. It has been suggested that sensitization to tobacco or to pneumococci resident in the lower respiratory tract results in increased levels of IgE or that the increased epithelial permeability which occurs in smokers [132] allows penetration of allergens into the airway wall, accounting for the increased IgE [133]. However, there is no evidence of an increased prevalence of a family history of allergic disease nor an increased prevalence of positive skin tests to common aeroallergens

in smokers [119]. The relationship between increased IgE levels and age and pack-years smoked, and the fact that the levels decline following cessation of smoking [116], again suggests an acquired rather than constitutional cause for the raised IgE in cigarette smokers.

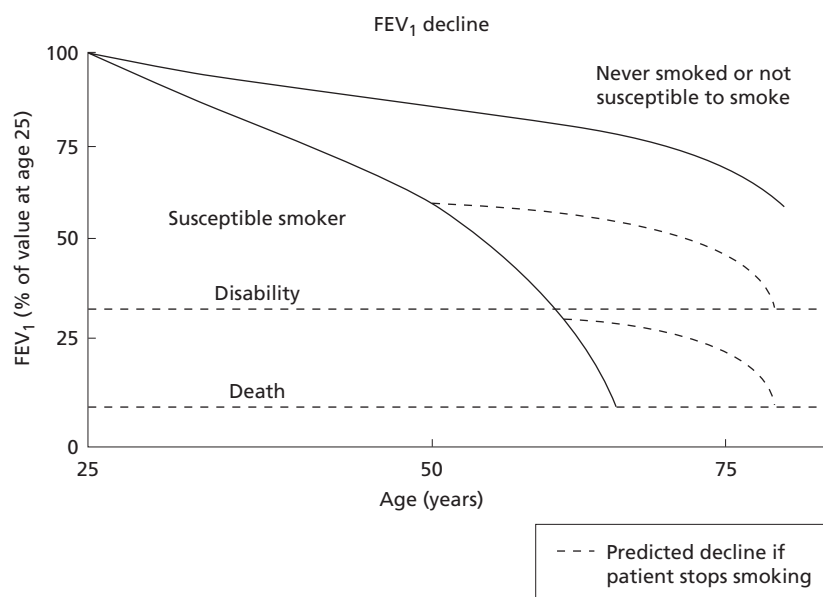

An important question is whether AHR is an important risk factor for the development of progressive airways obstruction in smokers. Since atopy and cigarette smoking occur in 30% of the population, the clear relationships between total IgE, positive skin tests, aeroallergens and AHR that occur in asthma are likely to be found also in population studies which include smokers. Smoking is not rare in asthmatics [134] but does not appear to be a risk factor for the development of asthma in middle age [135]. Indeed asthma may first develop after quitting smoking [136].

The role of AHR in the pathogenesis of airways obstruction remains unclear. It has been suggested that persistent airways obstruction in middle-aged subjects may be of two types. The first, as in the 'Dutch hypothesis', is associated with an asthmatic predisposition with associated allergic phenomenon in which AHR may be important in the pathogenesis of persistent airways obstruction [137]. In the second type, which may be considered to represent the emphysematous type of COPD, AHR may result from structural changes as described above and therefore has no significant pathogenic role in the accelerated decline in respiratory function. However, it is clear that there may be considerable clinical overlap between these two types of individuals.

## Natural history and prognosis

Severe airways obstruction in patients with COPD is

thought to occur in susceptible smokers as a result of years of accelerated decline in  $FEV_1$ . In non-smokers, the  $FEV_1$  declines at a rate of 20–30 mL/year [138] (Fig. 23.6). Smokers have an accelerated decline in  $FEV_1$  and the rate increases with increasing numbers of cigarettes smoked. Reported changes in  $FEV_1$  in patients with COPD range from 48 to 91 mL/year [36]. Fletcher and colleagues [23] found a relationship between the level of  $FEV_1$  and the annual rate of decline in  $FEV_1$  over a follow-up period of 8 years in a study of working men in London. From these data they suggested that susceptible cigarette smokers could be identified in early middle age by a reduction in  $FEV_1$  (Fig. 23.6). They assumed that there was a 'tracking' effect, whereby individuals in the highest or lowest  $FEV_1$  percentiles remained in the same percentiles over subsequent years. However, there is one other model for the development of impairment of  $FEV_1$  in the susceptible smoker: smoking-related lung damage occurs as a result of inflammation and eventual scarring of the small or peripheral airways, in which extensive changes may occur without any resultant change in tests of overall lung function, such as  $FEV_1$ . Thus such susceptible smokers might only present with an accelerated decline in  $FEV_1$  at a late stage of the disease, whereas at an earlier stage they would be indistinguishable from the general population of smokers, although having a lower  $FEV_1$  than people who never smoked. Support for the 'tracking' effect comes from a study of 2718 working men whose pulmonary function was assessed in the 1950s and subsequently followed up over 20 years. In this cohort, in those whose initial  $FEV_1$  was more than 2 SD below predicted values, the risk of death from chronic airways obstruction was 50 times greater than in those whose initial  $FEV_1$  was above average [28]. Similar results have been reported from

**Fig. 23.6** The effect of age on airflow obstruction in normal subjects and susceptible cigarette smokers. Cessation of smoking returns the rate of decline to normal. (Adapted from Fletcher *et al.* [23].)

population studies in Copenhagen [29] and from studies in six US cities [94]. The presence of tracking for the decline in  $FEV_1$  has been confirmed in middle-aged males in studies from Tucson, Arizona, but not in women smokers [139]. Furthermore, there is a tendency for annual rates of decline in  $FEV_1$  to be slower in advanced compared with mild disease [36]. There are large differences in the rate of decline between individuals in longitudinal studies. It is presumed that those who develop severe airways obstruction are those who have the fastest decline in  $FEV_1$ . Other tests sensitive to changes in peripheral airways and airspaces, such as the single-breath nitrogen test or maximum expiratory flows below 50% of vital capacity on a flow-volume curve, are abnormal when the  $FEV_1$  is normal in almost all smokers who subsequently develop a reduced  $FEV_1$  [140]. However, not all patients with an abnormal single-breath nitrogen test develop a reduced  $FEV_1$ , which has limited the value of this test. Small changes in the carbon monoxide diffusion coefficient ( $K_{CO}$ ) occur in many cigarette smokers [141] and often reverse as a result of stopping smoking, suggesting removal of a pulmonary vascular response. In some smokers there is a considerable reduction in  $K_{CO}$  at a time when spirometry is relatively well preserved [142]. There is very limited information on follow-up studies of  $K_{CO}$  or indeed of sequential measurements of lung recoil pressure [143], which is also abnormal in the early stages of airways obstruction [142,143].

### Effects of smoking cessation

Most studies of the effects of stopping smoking have been made in middle-aged or older subjects with mild airways obstruction. After smoking cessation these subjects have a rate of decline in  $FEV_1$  that approaches that found in people who have never smoked [23,32,138]. Most cross-sectional studies show a slightly higher mean  $FEV_1$  in ex-smokers than in current smokers [30,32,144]. Longitudinal measurements in the Lung Health Study demonstrated a slight improvement in  $FEV_1$  in the first months after stopping smoking in younger subjects with very mild impairment of lung function, but a subsequently slower decline than in continuing smokers [37]. Short-term studies of stopping smoking have shown improvement in small airway tests, such as the single-breath nitrogen test, although changes in maximum expiratory flow-volume curves have been variable [145]. However, a clear improvement in survival has been demonstrated in ex-smokers with advanced disease [36,38].

### Prognosis

The strongest predictors of survival in patients with COPD are age and baseline  $FEV_1$  [36]. Less than 50% of patients whose  $FEV_1$  has fallen to 30% of predicted are

alive 5 years later [146]. There is an even stronger relationship between survival and the  $FEV_1$  after, rather than before, the use of bronchodilators. Other unfavourable prognostic factors include severe hypoxaemia, a high pulmonary arterial pressure and low  $K_{CO}$ , which become apparent in patients with severe disease [36,146]. The factors that favour improved survival are stopping smoking and a large bronchodilator response. A reduced  $FEV_1$  is also a predictor of later cardiovascular mortality [96,147] and is an important additional risk factor for lung cancer, independent of age or cigarette smoking [148].

The only treatment shown to improve the long-term prognosis in patients with COPD is long-term domiciliary oxygen therapy, given for at least 15 h daily [149,150]. The use of intermittent positive pressure breathing, at least in non-hypoxaemic patients, has failed to improve survival [151]. Furthermore, regular inhaled muscarinic antagonists in the Lung Health Study did not slow the decline in  $FEV_1$  over a 5-year period [37]. Trials of long-term inhaled corticosteroids in two European studies [152,153] in mild COPD and preliminary results from another trial in moderate to severe COPD have failed to show that inhaled corticosteroids have no effect on the rate of decline in  $FEV_1$  (see p. 677).

### Pathology

The pathological changes in patients with COPD are complex and occur in both the large and small airways, and in the alveolar compartment. The difficulty in distinguishing, clinically or by respiratory function tests, the relative contributions that the pathological changes in the airways and emphysema make to the airways obstruction has been the subject of considerable study. In general, in all such 'structure-function' studies pathological changes correlate rather poorly with both clinical and functional patterns of the disease [154]. There are several reasons for this, including the fact that most studies that correlated pathological changes with function were performed on patients with relatively mild disease who were undergoing lung resection or, alternatively, were studies of autopsy material in patients with end-stage COPD. Sampling problems occur in the study of resected lung specimens when only a single lobe is resected. Other problems with these studies include the reliance on semi-quantitative scoring techniques to measure the extent of emphysema or inflammation and the inability in pathological material to recognize functional abnormalities such as bronchoconstriction.

As a result there is still no clear consensus on whether the fixed airway obstruction in COPD is largely due to inflammation and scarring in the small airways, resulting in narrowing of the airway lumen, or to loss of support to the airways because of loss of alveolar walls as in emphysema. Although the pathology of COPD is complex, it can be

simplified by considering separately the three sites at which pathological changes could, in smokers, produce a clinical pattern of largely fixed airways obstruction. These are the bronchi, where chronic bronchitis develops; the alveolar compartment, where emphysema develops; and the more peripheral airways, which develop so-called 'small airways disease'. The clinicopathological picture is complicated by the fact that these three entities, or any combination of the three, may exist in an individual patient.

### Chronic bronchitis

The pathological basis for the hypersecretion of mucus, which defines this condition clinically, is an increase in the volume of the submucosal glands and an increase in the number and change in distribution of goblet cells in the surface epithelium. Submucosal glands are confined to the bronchi, decreasing in number and size in the smaller more peripheral bronchi, but are not present in the bronchioles. In chronic bronchitis, the hypertrophy of the mucus-secreting glands was thought to be largely a consequence of the irritant action of cigarette smoke [155]. However, in animal experiments chemical stimuli, such as sulphur dioxide and nitrogen dioxide, can also result in mucous gland hypertrophy [156]. The hypertrophy of mucous glands is mainly in the larger bronchi and is evenly distributed throughout the lungs [157]. Mucous gland hypertrophy can be quantified by the Reid index [158], which is the ratio of the distance between the basement membrane of the airway epithelium and the cartilage to the thickness of the gland layer, normally 3:1. Alternatively, mucous gland size can be assessed by measurement of the absolute gland area, whereby the proportion of the wall volume occupied by glands is assessed. The Reid index was devised in an attempt to assess the gland mass independent of variations in bronchial dimensions. However, measurements of sputum production correlate better with mucous gland area or volume than with the Reid index. Neither sputum production nor gland size bear any relation to antemortem FEV<sub>1</sub> [159]. Furthermore, infection does not appear to be an aetiological factor in the bronchial mucous gland hypertrophy in chronic bronchitis [160].

In healthy people who have never smoked, goblet cells are seen predominantly in the proximal airways and decrease in number in more distal airways, being normally absent in terminal or respiratory bronchioles [161]. In contrast, in smokers, goblet cells not only increase in number but extend more peripherally [161]. The presence of metaplastic or dysplastic changes in the surface epithelium in smokers may replace the goblet cells of the normal respiratory epithelium and hence may reduce the numbers of goblet cells in the proximal airways in some smokers. Since the mass of the submucosal glands is greater than that of the goblet cells, most airway secretions are produced by the glands and there is a relationship

between the extent of the submucosal glands and the volume of sputum production [162].

Smaller peripheral bronchi may be thickened and distorted by scar tissue. Loss of cartilage in the subsegmental bronchi has been described by some authors and this may render the bronchi more susceptible to expiratory collapse [163]. Some authors have suggested that scarring of the smaller airways and airway inflammation is associated with airways obstruction [164,165]. In most studies the assessment of airway inflammation has been semi-quantitative. In one study of resected lung specimens, there was no significant relationship between a decrease in bronchiolar lumen size and measurements of airways obstruction [166].

In the presence of acute infection the bronchial walls may be macroscopically inflamed and there may be pus in the lumen. Microscopically, the bronchial walls may show infiltration with acute or chronic inflammatory cells associated with dilatation of the capillaries and oedema. The mucous membrane may become ulcerated, with squamous epithelium replacing columnar epithelium in limited areas.

### Bronchial biopsy studies

The use of bronchoscopy to obtain airway cells by bronchoalveolar lavage (BAL) and bronchial tissue samples by biopsy has added new insights into the role of inflammation in both asthma and COPD [167,168]. However, bronchoscopy is an invasive technique and recent work has suggested that examination of spontaneous or induced sputum may be an effective non-invasive method to investigate the inflammatory cells in the airways of patients with COPD [169].

Early studies reported an increased number of neutrophils in BAL fluid in COPD [170]. Although these studies characterizing the inflammation in the large airways are of some interest, the increase in airflow limitation in COPD is considered to reside largely in the peripheral airways [171]. Bronchial biopsy studies have recently described the inflammation in the bronchi of patients with chronic bronchitis, with or without airways obstruction, in much the same way as has been done in asthma [167]. These have confirmed the findings of earlier studies of resected lung material, which showed inflammation in the bronchial walls in this condition [98,172]. As with asthma, studies of bronchial biopsies in patients with chronic bronchitis have shown that activated T lymphocytes are prominent in the proximal airway walls [100]. However, in contrast to asthma, macrophages are also a prominent feature and the CD8 suppressor T-lymphocyte subset, rather than the CD4 subset, predominates. Recently, O'Shaughnessy and coworkers [173] have shown a significant negative association between the numbers of CD8+ cells in the airway walls and the degree of airways obstruction as measured by FEV<sub>1</sub> in a group of smokers. There is also a greater number of T lymphocytes and

macrophages in the bronchial walls of patients with chronic bronchitis who also have airways obstruction [173,174]. Bronchial biopsies from patients experiencing an exacerbation of chronic bronchitis indicate increased numbers of eosinophils in the bronchial walls [175], although their numbers are small in relation to the numbers present in exacerbations of asthma and, in contrast to asthmatics, these cells do not appear to have degranulated [176].

Several studies, using BAL [177,178] or spontaneous or induced sputum [178–180], have demonstrated intraluminal inflammation in the airspaces in patients with chronic bronchitis, with or without airways obstruction. There are clear differences between the cell populations sampled by these different techniques [178]. In stable chronic bronchitis the percentage of neutrophils was significantly higher in sputum than in BAL, whereas the reverse was true for macrophages and lymphocytes. The lymphocyte was the predominant cell infiltrating the bronchial submucosa. However, there was fairly good agreement between the numbers of eosinophils counted by the three techniques in exacerbations of chronic bronchitis [178]. The pathogenic significance of these findings awaits further study, and the question of a possible overlap with asthma in these subjects arises. Studies of spontaneous or induced sputum in patients with chronic bronchitis also indicate the presence of chemotactic activity, partly due to interleukin 8 and also other inflammatory mediators, such as tumour necrosis factor [179,180]. There is also some preliminary evidence that treatment with anti-inflammatory agents such as inhaled steroids can reduce the chemotactic activity of sputum, and thus play a protective role by decreasing the recruitment of neutrophils into the airspaces [179]. However, other studies have shown no effect of oral or inhaled corticosteroids on cytokine levels in induced sputum in COPD patients [180a].

Cigarette smoking is associated with an increased sequestration of neutrophils in the pulmonary microvasculature, which also occurs during exacerbations of COPD [181,182]. Increased neutrophil sequestration is due initially to a decrease in the deformability of circulating neutrophils, which delays their passage as they deform in order to pass through the smaller pulmonary capillaries [183,184]. The increased sequestration in, and migration of neutrophils from, the circulation in patients with COPD involves the upregulation of cell-surface adhesion molecules on endothelial and epithelial cells [185]. There is also some evidence that the airspace inflammation in patients with chronic bronchitis persists following smoking cessation, if the production of sputum persists [186].

These studies of sputum and bronchial biopsies in chronic bronchitis have mainly sampled the proximal airways. Recent preliminary studies suggest that inflammatory changes present in the large airways may reflect those present in the small airways and perhaps even those in the alveolar walls [187,188].

## Emphysema

The original definitions of emphysema by the Ciba Guest Symposium in 1959 [189] and by the ATS in 1962 [190] were modified as a result of a National Heart, Lung and Blood Institute workshop in the USA in 1985 [6], which defined emphysema as 'a condition of the lung characterized by abnormal, permanent enlargement of the airspaces, distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis'.

This is a morphological definition more relevant to the pathologist than to the clinician. It should be emphasized that clinical, radiographic and functional assessment of patients is an insensitive method of diagnosing emphysema. Dividing pulmonary emphysema into its subtypes could, until recent studies using high resolution CT scanning, only be undertaken by the pathologist. However, the definition of emphysema also presents problems for the pathologist, since there are no agreed criteria for normal airspace size by which abnormality can be assessed. Although the statement 'without obvious fibrosis' was included in the definition to exclude enlarged airspaces associated with gross fibrosis, as in cryptogenic fibrosing alveolitis, it is recognized that fibrosis is found in the walls of emphysematous spaces [191]. A further problem for the pathologist is the concept that the presence of emphysema implies that there has been enlargement of airspaces resulting from destruction of alveolar walls. This, by definition, excludes other conditions where overinflation is present, such as after pneumonectomy or in chronic asthma. However, in an area of established emphysema it is not possible to determine whether the absence of airspace walls has been due to a destructive process.

Emphysema has been classified by the pattern of enlarged airspaces on the cut surface of a fixed inflated lung. Air-space enlargement can be identified macroscopically when the airspace size reaches 1 mm. The distribution of these enlarged airspaces is identified within the acinar unit [158]. Three major types of emphysema are recognized, according to the distribution of enlarged airspaces within the acinar unit (Fig. 23.7).

**1 Centriacinar (syn. centrilobular) emphysema**, in which enlarged airspaces are initially clustered around the terminal bronchiole.

**2 Panacinar (syn. panlobular) emphysema**, where the enlarged airspaces are distributed throughout the acinar unit.

**3 Periacinar (syn. paraseptal or distal acinar) emphysema**, where the enlarged airspaces are along the edge of the acinar unit but only where it abuts against a fixed structure, such as the pleura or a vessel.

Periacinar emphysema occurs less commonly than centriacinar or panacinar emphysema and is usually of little clinical significance, except when it occurs extensively in a subpleural position and may be associated with

**Fig. 23.7** Distribution of abnormal airspaces within the acinar unit in different types of emphysema: (a) normal lung; (b) focal enlargement of airspaces around the respiratory bronchioles in centriacinar emphysema; (c) confluent, even involvement of the acinar unit in panacinar emphysema; (d) peripherally distributed enlarged airspaces abutting the pleura in paraseptal emphysema. (From Lamb [420] with permission.)

pneumothorax. Two other types of emphysematous change have been described.

**4** Scar or irregular emphysema is used to describe enlarged airspaces around the margins of a scar, unrelated to the structure of the acinus. This lesion is excluded from the current definition of emphysema but is a useful descriptive term.

**5** Bullae represent localized areas of emphysema that have overdistended. Conventionally, only lesions greater than 1 cm are described as bullae [189]. The terms 'bullae', 'cyst', 'cavity' and 'pneumatocele' are often used interchangeably. A cyst is a generic term for an abnormal airspace greater than 1 cm in diameter, which can be congenital or acquired, such as a cavity, bulla or pneumatocele, all of which lack an epithelial lining. A cavity is an acquired cyst with non-epithelial lining and a wall thicker than 3 mm. These usually arise following pulmonary infection or fibrosis. A bulla is also an acquired enlarged airspace but has extremely thin walls of minimal thickness. The term 'pneumatocele' is usually reserved for small postinfective cysts that result from tissue lysis, such as in staphylococcal pneumonia.

Bullae arise in an area of lung that has been locally destroyed, although this destruction does not always have

to be as a result of emphysema and can also occur from lytic or traumatic causes. Bullae have been described in tuberculosis, sarcoidosis, AIDS and trauma [192]. In a minority of cases, around 20%, the surrounding lung is normal, but in the majority there is associated emphysema and chronic airways obstruction [192].

Bullae have been classified according to their size and position [193]. Type I bullae have a narrow neck, attached to a mushroom-like expansion into the pleural space; type II bullae have a broader neck, and represent distension of a moderate area of emphysema; and type III bullae occur in an area of severe emphysema within the lung and have no pleural reflection. The origins of bullae remain obscure, particularly type I [193]. Types II and III appear to arise in areas of moderate to severe emphysema. One hypothesis is that a region of local weakness in the structure of the lung is supplied by airways with a valvular structure, which allows gas to enter but impedes its exit. However, there are several problems with this theory, since it would suggest that gas enters an area of high pressure rather than distending more compliant lung. Furthermore, direct measurement of pressures within bullae measured at operation are very similar to pleural pressure [193] ( $-11$  cmH<sub>2</sub>O during tidal breathing). This is despite the appearance of bullae at operation, which give the impression of a structure containing gas under pressure. This paradoxical finding may result from the development of positive end-expiratory pressure within bullae during intermittent positive pressure ventilation during thoracotomy, resulting in artificially high pressures in the interior of the bulla that are greater than pleural pressure.

The two common types of emphysema have different distributions within the lungs. Centriacinar emphysema is more common in the upper zones of the upper and lower lobes [194], whereas panacinar emphysema may be found anywhere in the lungs but is more prominent at the bases and may be associated with  $\alpha_1$ -AT deficiency. Both types of emphysema can occur alone or in combination.

There is still debate over whether centriacinar and panacinar emphysema represent different disease processes [194,195], and hence have different aetiologies, or whether panacinar emphysema is a progression from centriacinar emphysema [196,197]. There is certainly a clearer association between cigarette smoking and centriacinar emphysema than with panacinar emphysema [198]. Indeed in surgically resected lungs the presence of centriacinar emphysema is independent of the occurrence of microscopic panacinar emphysema [199,200]. Recent studies of the morphometry and inflammatory cell populations in lungs in these two patterns of emphysema also suggest that different pathogenic mechanisms may result in these two forms of emphysema. In studies of resected lungs, Kim and coworkers [199] and Saetta and colleagues [200] showed that smokers can develop both centriacinar and panacinar emphysema, and that those patients with

centriacinar emphysema had more abnormalities in their small airways, with more muscle and smaller luminal diameters, than those with predominantly panacinar emphysema. Moreover, the patients with centriacinar emphysema had greater AHR than those with panacinar emphysema; the AHR in the former correlated with the numbers of lymphocytes in the airway walls [201].

The severity of emphysema can be measured either macroscopically or microscopically in resected lung specimens. Macroscopic emphysema can be assessed by the point counting technique [202], where a grid of intersecting points is placed over the lung and the type of tissue (normal or emphysematous) a point overlies is recorded, producing a quantitative assessment of the amount of lung involved in macroscopic emphysema. Various emphysema grading techniques have been described, the best known being that of Thurlbeck and coworkers [203] who used a series of paper-mounted cross-sections of lungs with varying degrees of emphysema that were ranked from 0 (normal) to 100, which was the most extensive emphysema encountered in a series of 500 paper-mounted sections. However, this is a semi-quantitative technique that grades emphysema on a non-linear scale, since a score of 80 is not double a score of 40. Furthermore, none of these techniques makes any assessment of the pattern of emphysema. In addition all these techniques fail to identify airspaces less than 1 mm in diameter and therefore to do not measure microscopic emphysema. This is important since when an alveolus, which is normally 240  $\mu\text{m}$  in diameter, has enlarged to reach 1 mm, 75% of the alveolar surface has been destroyed [204].

Various techniques have been used to quantify microscopic emphysema including the mean linear intercept technique, which estimates the diameter of the airspaces [205]. Advances in image analysis have allowed automation of this previously time-consuming technique,

enabling detailed analysis of large numbers of lung samples [206]. Measurements of microscopic emphysema can be expressed in terms of the distal airspace size (mean linear intercept,  $L_m$ ) or in terms of the surface area of the alveolar or airspace wall per unit lung volume (AWUV) [207,208].

These quantitative morphometric techniques have begun to allow a definition of normality for airspace size. Gillooly and Lamb [209] studied lungs from a group of 38 lifelong non-smokers with a wide age range and have defined normality as values of AWUV lying outwith the 95% confidence limits of their measurements (Fig. 23.8). Using similar techniques in a population of smokers, the majority of smokers lie within the normal range. Interestingly, there was no difference in the smoking histories between those lying in or outwith the normal range. This exaggerated fall in AWUV in some smokers is the result of microscopic, panacinar emphysema, which was found in only 26% of the smoking group. Thus panacinar emphysema does not appear to be present at an early stage in all smokers. The relationship between AWUV and centriacinar emphysema is less clear since its focal nature has little effect on the overall mean airspace size, as expressed by AWUV. The fall in airspace wall surface area with age was previously thought to represent 'senile emphysema'. However, these recent studies suggest that this enlargement of distal airspace size may be part of the normal ageing process [209].

Absence of fibrosis is a prerequisite in the most recent definition of emphysema [6]. Histologically, however, fibrosis has been recognized in the region of the terminal or respiratory bronchioles, as part of a respiratory bronchiolitis described by Niewoehner and colleagues [210] that occurs in asymptomatic cigarette smokers. Furthermore, when sensitive techniques are used to measure collagen and elastin in alveolar walls, there appears to be an

**Fig. 23.8** The effect of smoking on mean alveolar or airspace wall per unit lung volume (AWUV) values. The dotted lines indicate the normal range derived from a population of non-smokers. Those lying outwith the normal range have microscopic panacinar emphysema that does not appear to be related to smoking dose. (From Gillooly & Lamb [209] with permission.)

increase in collagen in the lung parenchyma in smokers compared with non-smokers [211], which is also the case in areas of emphysematous compared with areas of relatively normal lung [212]. Scanning electron microscopy has also demonstrated fibrosis in association with end-stage emphysema [213].

The destruction of airspace walls has been assessed by Saetta and colleagues [200], who described a destructive index based on a point counting technique that estimated the proportion of the airspace walls showing evidence of damage according to set criteria. Using this technique alveolar wall damage has been described in the absence of measurable emphysema [195,200].

The bronchioles and small bronchi are supported by the attachment to the outer aspect of their walls of adjacent alveolar walls. This arrangement maintains the tubular integrity of the airways. It has been suggested that loss of these attachments may lead to distortion and irregularity of airways, which may result in airflow limitation [214,215] (Fig. 23.9). The integrity of the alveolar wall supports can be assessed by measuring the linear distance between alveolar wall attachments, the interalveolar wall attachment distance (IAAD) [216,217]. Increase in IAAD may be caused by local inflammatory changes and could result in early airway collapse during expiration, and hence contribute to the airflow limitation.

### Small airways disease

Hogg, Macklem and Thurlbeck introduced the concept of 'small airways disease' in studies of lungs *in vitro*. Using a retrograde catheter they were able to show that the increased flow resistance in the lungs of patients with COPD largely occurred in the small airways at the periph-

ery of the lungs [171]. Subsequent studies by Niewoehner and colleagues [210] on postmortem lungs obtained from young asymptomatic cigarette smokers who died of non-respiratory causes and studies by Cosio and coworkers [218] in resected lungs demonstrated several different pathological changes in small airways. These were assessed using a scoring system by Cosio and colleagues [218] as follows:

- 1 occlusion of the lumen by mucus and cells;
- 2 presence or absence of mucosal ulceration;
- 3 goblet cell hyperplasia;
- 4 squamous cell metaplasia;
- 5 inflammatory infiltrate in the airway wall;
- 6 amount of fibrosis in the airway wall;
- 7 amount of muscle;
- 8 degree of pigmentation.

From this subjective grading system a set of standard illustrations was made of the various grades of abnormality, termed the small airways disease score [219]. Others have used a more quantitative approach by measuring the dimensions of small airways. This is problematic since in histological sections most airways are sectioned tangentially. Many workers who have made measurements of small airways have ignored the associated alveolar walls that support the airways and which, as described above, can be selectively lost in microscopic emphysema, leading to tortuosity of the small airways [214,215]. Loss of these alveolar attachments may have an important role in the development of airways obstruction in early emphysema, but may be less important in the overall severity of airflow limitation in the later stages of the disease [220].

### Pathology of severe COPD

Most of the descriptions of the pathology of COPD described so far in this chapter have come from the study of resected lungs from patients who have early disease, since they are required to have sufficient respiratory reserve to allow surgery to proceed. These pathological changes may occur at the mild end of a spectrum of

**Fig. 23.9** (a) Cross-section of a small peripheral bronchiole showing a circular outline supported by adjacent alveolar walls. (b) A small bronchiole at the same magnification in a patient with very early macroscopic emphysema. The loss of alveolar supporting walls results in an elliptical airway.

(a)

(b)

disease that leads to end-stage COPD or may represent smoking-related changes, which may or may not progress. At autopsy in patients dying with end-stage COPD, severe macroscopic emphysema is the most prominent feature [221–223]. Centriacinar or panacinar emphysema may predominate, or there may be a mixture of both. Centriacinar emphysema is much more extensive and the lesions are larger in end-stage COPD than those seen in smokers without airways obstruction. Centriacinar lesions are usually confined to the upper zones of the lungs but extend throughout the lungs in patients with severe disease. Panacinar emphysema may also be widespread throughout the lungs. Type I and type III bullae are often present, both at the apex and on the diaphragmatic surface of the lower lobe. It is common to find mucous plugging and areas of bronchopneumonia at autopsy in patients with severe COPD, particularly in the lower lobes, and lung cancer is more common in these patients than one would expect from their smoking history [224].

### **Pulmonary vasculature**

The development of chronic alveolar hypoxia in patients with COPD produces characteristic remodelling of the pulmonary arteries that consists of three components. The first is an extension of the medial muscle into the pulmonary arterioles, which normally have no muscle in their walls [225,226]. The second is the presence of longitudinal smooth muscle in the intima of the small pulmonary arteries. Through a process of proliferation this muscle becomes progressively thicker and may eventually occlude the vascular lumen. Intimal fibrosis may occur that may be severe. However the significance of this is uncertain since it is clearly present in smokers without COPD [226,227]. The third component occurs in the small pulmonary arteries, which develop inner muscular tubes. External to the thickened elastic lamina is an area containing myofibroblasts. Internal to this is a coat of circular muscle bound by two elastic laminae. The zone containing myofibroblasts is eventually replaced by fibroelastic tissue.

In the large pulmonary arteries intimal atheroma may be present and the main pulmonary trunks may show aneurysmal dilatation, sometimes containing laminated thrombus, seen in about 20% of cases of severe COPD at postmortem. Attempts to quantify these structural abnormalities in the pulmonary vasculature and relate them to the degree of pulmonary hypertension is complicated by the fact that vasoconstriction, which can be seen in postmortem specimens, may alter morphometric measurements [228].

### **Heart**

Right ventricular hypertrophy and pulmonary hyperten-

sion are commonly found in patients with COPD who have chronic hypoxaemia [223]. Right ventricular hypertrophy can be measured at postmortem as the Fulton index, the ratio of the weight of the left ventricle and the interventricular septum to that of the free right ventricular wall. This ratio is normally greater than 2.2. Measurement of ventricular wall thickness alone is not considered accurate in the assessment of right ventricular hypertrophy due to the complicating effects of ventricular dilatation and heart failure [229].

Other abnormalities have been described in patients with hypoxic COPD, including a decrease in the muscle and weight of the diaphragm with increasing emphysema [230], enlargement of the renal glomeruli [231] and carotid body enlargement [232].

### **Structure–function relationships**

There are several limitations to structure–function studies in the lungs of patients with COPD. Early studies were largely performed on postmortem lungs in patients with end-stage lung disease and concentrated largely on macroscopic emphysema [194]. More recent studies have been undertaken in patients undergoing lung resection for peripheral bronchial carcinoma, where measurements of small airways disease and macroscopic and microscopic emphysema have been related to tests of respiratory function. In postmortem studies there is often a poor temporal relationship between respiratory function and the pathological assessment, whereas in surgically resected lungs respiratory function measurements have been made pre-operatively. However, these studies tend to be restricted to those with mild disease who are capable of undergoing thoracotomy. More recently CT (see below) has been used to quantify emphysema in life and has been related to both pathological measurements and lung function [8].

### **Emphysema**

There is a relatively poor relationship between semi-quantitative assessments of macroscopic emphysema and the severity of airways obstruction [221,222]. In a large study of 163 patients undergoing lung resection who had variable degrees of emphysema as assessed semi-quantitatively by the scoring system of Thurlbeck, there was no correlation between percentage predicted FEV<sub>1</sub> and the emphysema score [154]. Measurements of microscopic emphysema have also shown poor correlations with FEV<sub>1</sub> [208]. Several authors have stressed the importance of peribronchial alveolar attachments in maintaining airway shape [214,215]. Loss of airway attachments as described above appears to be related to the degree of airflow limitation. Support for this comes from both post-mortem studies [233] and studies of the early stages of the disease, where a relationship has been shown between a

decrease in  $FEV_1$  and loss of alveolar attachments [216,217]. Indeed in patients with mild COPD, Lamb and coworkers [216] showed that the best relationship with percentage predicted  $FEV_1$  was the Inter-alveolar cell attachment distance (IAAD). These workers also showed a relationship between IAAD and the slope of the single-breath nitrogen test, suggesting that loss of attachments leads to lack of homogeneity in the distribution of ventilation in the lungs.

A relationship between single-breath and steady-state  $K_{CO}$  and the degree of emphysema has also been shown in several studies [207,208,234]. However, the relationship between  $K_{CO}$  and measurements of microscopic emphysema, either  $L_m$  or AWUV (see p. 631), is closer than that between  $K_{CO}$  and measurements of macroscopic emphysema [207,208].

It has been suggested that changes in the elastic recoil of the lungs should bear the closest relationship to the severity of emphysema [235,236]. An exponential equation

$$V = a - be^{-kp}$$

can be fitted to the pressure–volume relationship of the lungs. The constant  $k$  from this equation describes the shape of the curve [237]. Studies on a group of 163 patients with variable degrees of emphysema showed no significant relationship between the exponential constant  $k$  and the macroscopic emphysema score [154]. Since the elastic recoil of the lungs is one of the major determinants of maximum expiratory flow, the lack of a relationship between macroscopic emphysema and the elastic recoil of the lungs may explain the lack of correlation between macroscopic emphysema and  $FEV_1$ . These authors suggested that patients who had decreased elastic recoil (i.e. increased  $k$ ) had evidence of microscopic emphysema, as measured by increased values of  $L_m$ , irrespective of the absence or presence of macroscopic emphysema [154]. This suggests that  $k$  reflects the structure of the lung *apart* from the macroscopic emphysematous lesions.

## Pathogenesis of COPD

Since COPD encompasses at least three pathological conditions, chronic bronchitis, emphysema and small airways disease or respiratory bronchiolitis, it is a difficult task to encompass these diverse pathologies in one simple pathogenic mechanism. The main aetiological factor in COPD is cigarette smoking, but it is clear that susceptibility to the effects of cigarette smoke determines the presence and the degree of COPD since only 15–20% of smokers develop the disease.

The majority of the work on the pathogenesis of COPD relates to the development of emphysema and derives from the observation of an association between a deficiency of  $\alpha_1$ -AT and the development of early-onset emphysema, which was first described by Laurell and

Ericksson in 1963 [71]. A second important observation was made in the same year by Gross and coworkers [238] who described the first animal model of emphysema, produced by instillation of the proteolytic enzyme papain into the rat lung.

These two important observations form the basis of the protease–antiprotease theory of the pathogenesis of emphysema. The hypothesis states that in healthy lungs the release of proteolytic enzymes from inflammatory cells does not cause lung damage because of inactivation of these proteolytic enzymes by an excess of inhibitors. However, in conditions of excessive enzyme load, or where there is an absolute or functional deficiency of antiprotease an imbalance develops between proteinases and antiproteinases in favour of proteinases, leading to uncontrolled enzyme activity and degradation of lung connective tissue in alveolar walls, leading to emphysema (Fig. 23.10). This simplified version of the theory has been elaborated over the past 15–20 years and an enormous amount of research has been focused on providing evidence to support it.

## Animal models

There have been numerous animal models of emphysema. However, many of these models involve single exposures to an insult and therefore cannot hope to mimic the repeated exposure to cigarette smoke that is thought to result in emphysema in humans. The most extensively studied of all animal models involves instillation of the protease elastase. In 1972 Lieberman [239] was the first to show that leucocyte enzymes could digest lungs deficient in  $\alpha_1$ -AT and that this could be prevented by exogenous  $\alpha_1$ -AT. The ability of purified neutrophil elastase to produce emphysema in experimental animals was demonstrated in 1977 [240] to be associated with a transient decrease in lung elastin [241]. These studies are unphysiological since instillation of elastase into the lung produces a profound inflammatory response that does not resemble the small influx of neutrophils which occurs in the lungs of cigarette smokers as a result of the repeated insult of smoking. However, these studies supported the contention that elastase was the most important proteolytic enzyme in the pathogenesis of emphysema.

## $\alpha_1$ -Antitrypsin/ $\alpha_1$ -protease inhibitor

The fact that subjects with  $\alpha_1$ -AT deficiency develop emphysema early in life, particularly if they smoke, provides a simple concept for the development of emphysema resulting from a disturbance in the balance between elastase release and its inactivation by  $\alpha_1$ -AT. It is considered that emphysema developed in the absence of  $\alpha_1$ -AT deficiency by:

- 1 an increase in the proteinase burden, due to either the presence of increased numbers of inflammatory leuco-

**Fig. 23.10** Simplified protease–antiprotease theory of the pathogenesis of emphysema. Neutrophils (N) sequester in the pulmonary capillaries initially as a result of the oxidant effect of cigarette smoke, which decreases neutrophil deformability. Activated neutrophils adhere to the endothelial cells and subsequently migrate into the airspaces. Oxidants, either directly from cigarette smoke or released from activated airspace neutrophils, inactivate antiproteases such as  $\alpha_1$ -protease inhibitor ( $\alpha_1$ -Pi syn.  $\alpha_1$ -AT), reducing its ability to bind to and hence inactivate proteases, particularly elastase. This allows active elastase to enter the lung interstitium and bind to and destroy elastin, causing destruction and enlargement of the distal airspace walls. This simplified protease–antiprotease theory is complicated by the presence of other antiproteases, such as antileucoprotease, and other proteases, such as metalloproteases released from macrophages (M). There is also the potential for neutrophils to be activated and release elastase while sequestered in the pulmonary capillaries without the need to migrate.

cytes in the airspaces or the release of excess protease from the leucocytes;

- 2 a functional deficiency of protease inhibitors;
- 3 a combination of 1 and 2;
- 4 an abnormality in the repair mechanisms for lung connective tissue.

$\alpha_1$ -AT is a potent inhibitor of serine proteases and has greatest affinity for the enzyme neutrophil elastase [242]. It is a 52-kDa glycoprotein synthesized in the liver, and increases from its usual plasma concentration of approximately 2 g/L as part of the acute-phase response. Most of the lung  $\alpha_1$ -AT is derived from the plasma, although monocytes and macrophages can also manufacture the protein. Chromosome 14 contains a single 12.2-kb gene that encodes the  $\alpha_1$ -AT protein [243]. The protein is composed of 394 amino acids and three carbohydrate side-chains. The gene for  $\alpha_1$ -AT is polymorphic, with over 70 known alleles, resulting from changes in the amino acid sequence, none of which alter protein structure, function or expression. The activity of the protein is critically dependent on the methionine-358, serine-359 sequence at its active site. The  $\alpha_1$ -AT protein is classified phenotypically by its electrophoretic properties, resulting in the Pi system. The common Pi type is M and the deficient Pi type, which can be clearly distinguished using electrophoresis is termed Z. The average  $\alpha_1$ -AT plasma levels for the more common phenotypes are shown in Table 23.3. Over 75 different Pi types of  $\alpha_1$ -AT have now been identified. Some alleles, such as Null Null, are associated with no detectable  $\alpha_1$ -AT.

The Z deficiency state (PiZ) is associated with PAS-

positive inclusion bodies in the liver, which represent accumulations of the  $\alpha_1$ -AT protein. Although liver and mononuclear cells from PiZ patients can manufacture normal amounts of mRNA [244] and the protein can be translated, there is little secretion of the protein [245]. It is now recognized that the Z  $\alpha_1$ -AT gene is normal except for a single point mutation resulting from substitution of a guanine for adenine in the DNA sequence that codes for the amino acid at position 342 on the molecule. This produces a change in the normal amino acid sequence from glutamic acid to glycine [246]. Recently the consequences of this change, and hence the mechanisms producing  $\alpha_1$ -AT deficiency, have been elucidated. It appears that the charge of the amino acid at position 342 is important to the function of the protein [247]. The glutamic acid at position 342 is sited at the base of the inhibitory active site loop. Substitution of glutamic acid by glycine results in alteration in the normal 'hinge' mechanism at this region, thus extending the active site loop which can then fit between the A sheets of a second molecule. This results in spontaneous polymerization of the protein [248]. The consequence is that large polymers of  $\alpha_1$ -AT accumulate in the liver and are unable to pass through the rough endoplasmic reticulum, so impairing  $\alpha_1$ -AT secretion. The mechanisms of the other deficiency states have also been elucidated [249].

### Epidemiological factors in $\alpha_1$ -AT deficiency

In the UK approximately 86% of the population are PiMM and have been used to establish the normal levels of  $\alpha_1$ -AT within the population (Table 23.3). The other phenotypes

**Table 23.3** Serum  $\alpha_1$ -proteinase inhibitor concentrations and the frequency of the more common phenotypes and the risk for emphysema. (Modified from Stockley & Afford [326].)

Phenotype	Percentage in UK population	Average concentration (g/L)	Risk factor for emphysema
MM	86	2	No
MS	9	1.6	No
MZ	3	1.2	No
SS	0.25	1.2	No
SZ	0.2	0.8	Yes
ZZ	0.03	0.4	Yes

are much less common and of these SZ and ZZ are associated with severe deficiency and MZ and SS with partial deficiency. The association between emphysema and severe deficiency of the ZZ [250], SZ and the rarer Null phenotypes [251] is well known. Other variants of  $\alpha_1$ -Pi (MZ, MS, SS), with serum levels greater than 50% of the values in PiMM subjects, are not definitely associated with an increased risk of developing COPD. PiSZ subjects have significantly lower serum  $\alpha_1$ -Pi levels than other heterozygotes. However, an increased risk of developing COPD has only been demonstrated in one study [252] but not in another two [253,254].

The commonest heterozygote phenotypes, MZ and MS, affect 3 and 8% of the UK population and these subjects have been extensively studied. Although hospital-based studies have shown a two- to five-fold excess of PiMZ in patients with COPD [255,256], population surveys have shown significant changes in spirometry only in PiZZ subjects [256] and either no [257] or only minor changes in lung elasticity have been demonstrated [258]. Only one prospective study of PiMZ subjects who smoked showed an accelerated annual decline in FEV<sub>1</sub> [259]. However, recent studies from the  $\alpha_1$ -AT registry in the USA indicate that although the PiSZ phenotype confers a significant risk of developing COPD in smokers, there is probably no added risk in non-smokers [260]. Thus whether the MZ phenotype is associated with an increased risk of emphysema remains controversial, but any effect is small in comparison to other risk factors.

Although the relationship between severe  $\alpha_1$ -AT deficiency and emphysema is well established, since few patients who have a PiZZ phenotype and who smoke survive beyond 60 years of age [34], it is clear that the number of patients identified as PiZZ is much less than can be predicted from the prevalence of the deficiency. Therefore some individuals with this deficiency do not develop severe airways obstruction [250]. The true prognosis of subjects with PiZZ is unknown, since many are clearly asymptomatic and therefore do not present themselves for detailed investigation. In Sweden, Larsson [34]

identified 246 PiZZ subjects from a population calculated to contain as many as 4000 individuals over the age of 20 with this phenotype. In the UK one would expect around 2000 PiZZ subjects between the ages of 45 and 55. However, in a national survey over several years, only 100 individuals were identified [250]. Although a number may have died from hepatic disease, it seems likely that a large proportion of PiZZ individuals do not develop any significant respiratory abnormalities and thus remain undetected. From the geographical distribution of the Z deficiency, the mutation is likely to have originated in Scandinavia and spread thereafter to north-western Europe. Deficiency of  $\alpha_1$ -AT in the serum also results in a deficiency in the lung lining fluid [261], since  $\alpha_1$ -AT enters the lung largely by diffusion from the plasma.

Since  $\alpha_1$ -AT is the only major inhibitor of neutrophil elastase in the lower airways [262], the presence of increased numbers of neutrophils in the lungs of subjects with  $\alpha_1$ -AT deficiency [261], attracted by increased release of chemotactic factors from alveolar macrophages [263], may create an increased elastase burden in the presence of an antielastase deficiency. It appears that the development of emphysema, and hence the decrease in life expectancy of  $\alpha_1$ -AT-deficient subjects, occurs particularly in the presence of the additional risk factor of smoking [34]. However, there are some patients who survive to old age with relatively well-preserved lung function even if they smoke. Thus our view of the natural history of  $\alpha_1$ -AT is biased since individuals are recognized, and therefore only followed up, when they develop symptoms and thus may not be representative of the whole population of  $\alpha_1$ -AT-deficient subjects. Greater identification of subjects with  $\alpha_1$ -AT deficiency who are asymptomatic and their follow-up should give new insights into the pathogenic mechanisms of the development of emphysema in these individuals.

### Pathogenesis of emphysema in patients without $\alpha_1$ -AT

The pathogenic mechanisms of emphysema and also of small airways disease in COPD is clearly more complex in patients without  $\alpha_1$ -AT deficiency. In this case the most clear association is with cigarette smoking. There are several possible mechanisms whereby cigarette smoke can alter the elastase–antielastase balance in the lungs, assuming that neutrophil elastase and  $\alpha_1$ -AT are the main players in this protease–antiprotease imbalance. In addition the role of other proteolytic enzymes derived from cells other than neutrophils have to be considered, as well as the effects of lung antiproteases other than  $\alpha_1$ -AT. Finally, there is the additional effect on retardation of elastin resynthesis by cigarette smoke, which has received much less research attention than that paid to the protease–antiprotease imbalance.

Since only 15–20% of cigarette smokers develop COPD, the question of susceptibility has to be considered. There are several pathogenic variables in the development of COPD, which may be genetically determined and may therefore play a significant role in the ultimate clinical course of patients who develop COPD. Such factors include the cellular response to tobacco, bronchial hyper-reactivity, variations in neutrophil and macrophage protease activity, protease inhibitor function and lung matrix injury and repair. Further understanding of the genetic determination of these factors may allow us to understand why some patients who smoke do not develop COPD, and why a significant portion of individuals who have homozygous  $\alpha_1$ -AT deficiency have not yet developed significant evidence of airways obstruction or pulmonary emphysema.

The mechanisms for the development of pulmonary emphysema can be conveniently described under three major headings: (i) increased protease burden; (ii) decreased antiprotease function; and (iii) decreased synthesis of elastin.

#### **Increase in protease burden**

An accumulating body of evidence supports a role for neutrophil elastase in the development of emphysema [81,264]. There are several processes by which the elastase burden could be increased in cigarette smokers:

- 1 increased sequestration and migration of neutrophils into the lungs in smokers;
- 2 neutrophils from susceptible smokers may contain increased amounts of elastase compared with non-susceptible smokers or control subjects;
- 3 neutrophils, once recruited, may show enhanced degranulation, leading to more connective tissue injury.

Under normal circumstances a proportion of the neutrophils are delayed or sequester while in transit in the pulmonary microvasculature [265]. This intravascular pool of neutrophils, which appears to be slow-moving within the pulmonary capillary segments or transiently adherent to the alveolar capillary endothelium, represents a source of cells that can migrate from the capillaries into the alveolar spaces in response to chemotactic stimuli. A small proportion of neutrophils migrate normally into the airspaces in response to inhaled allergens and toxins. The number of neutrophils in the airspaces is considerably increased in smokers [266]. In some studies a 10-fold increase in the number of neutrophils in BAL was demonstrated in smokers, although macrophages still remain the most predominant cell [267]. It appears that in some smokers an increased number of neutrophils become sequestered in the pulmonary microcirculation *during* smoking [182] via a mechanism that involves a decrease in the deformability of the neutrophils [184], so decreasing their ability to change their shape and pass through the

smaller diameter pulmonary capillary segments [104]. Once sequestered, the cells may be acted upon by cytokines to increase their adhesion to the endothelium and can migrate into the lung along chemotactic gradients. Although little is known of the details of this process in the lungs, there are several pieces of evidence that indicate enhanced chemotaxis in cigarette smokers.

Nicotine itself is chemotactic [268] and lung lavage fluids from smoke-exposed animals show increased chemotactic activity [269]. Chemotactic factors may also be released from bronchial epithelium [270]. There is some evidence suggesting a deficiency of a chemotactic factor inactivator in the serum of patients with  $\alpha_1$ -AT deficiency [271], which could lead to uncontrolled recruitment of neutrophils to the airspaces in these patients. It is possible that similar mechanisms play a role in patients without  $\alpha_1$ -AT deficiency. There is also evidence that circulating neutrophils are sensitized to chemotactic signals, even in passive smokers [272], and that neutrophils from patients with COPD show an enhanced response to standard chemotactic agents compared with non-smoking matched controls [273].

Some investigators have reported an association between blood leucocyte elastase concentrations and airflow obstruction in patients with  $\alpha_1$ -AT deficiency [274,275] while others have not [276,277]. Conflicting results also come from studies of patients with normal levels of  $\alpha_1$ -AT, some studies supporting the concept [276] while others do not [278]. The elastase content of neutrophils has a wide range in healthy subjects [273]. It may be that those subjects who develop COPD have neutrophils that, when activated, release more elastase. However, there is controversy over whether the elastase content of neutrophils in subjects with or without emphysema is increased [273,279]. Some support for this concept comes from studies which show that neutrophils harvested from peripheral blood from patients with emphysema degrade more fibronectin *in vitro* than cells from control subjects matched for age and smoking [273], an effect largely due to neutrophil elastase [280]. Other studies have shown that immunoreactive leucocyte elastase concentrations in the serum of patients with COPD are double those in age-matched controls [281]. However, the same is true in patients with other lung diseases, such as bronchiectasis. Thus although there is support for an increased protease burden from circulating leucocytes in patients with COPD, this association is not necessarily causal.

Studies that have sought evidence for increased elastolytic activity in the airspaces, as measured in BAL, have shown only a small increase in elastase-like activity in smokers compared with non-smokers [282,283]. Much of this activity appears to be due to metalloproteases [283]. There is a fourfold increase in macrophages in BAL in cigarette smokers [267]. These cells can secrete

cytokines, which cause neutrophil activation and degranulation and can also ingest and later release neutrophil elastase.

Enzymes other than neutrophil elastase have been identified in the lungs, including two present in neutrophils, cathepsin G and protease 3. Cathepsin G is a relatively weak elastolytic enzyme compared with neutrophil elastase [284] but can act synergistically with neutrophil elastase to degrade elastin [285]. Studies to date have failed to demonstrate that this protease can produce emphysema [286]. It is therefore unlikely that cathepsin G has a major role in elastin degradation alone and hence the development of emphysema. Protease 3 is another human neutrophil serine protease that has been shown to induce experimental emphysema [287]. It is more potent at degrading elastase than neutrophil elastase in acid pH (7.5) but is less potent at neutral pH [276]. This enzyme is also bactericidal [288]. The role of protease 3 in the development of pulmonary emphysema in humans has yet to be elucidated.

As mentioned above, macrophages have the ability to internalize and subsequently release elastase [289]. This fact has complicated the interpretation of earlier studies which showed that macrophages are capable of releasing elastolytic enzymes [290]. However, subsequent studies confirmed that human macrophages produce a metalloelastase [291] and other studies have shown that these cells also produce a cysteine protease (cathepsin L), which also degrades elastin at acidic pH [292]. Other studies have shown that cathepsin B is also present in macrophages [293]. Although several enzymes have the potential to degrade elastin, studies of BAL have not, as yet, provided any clear evidence to support a role for these other elastolytic enzymes in the pathogenesis of emphysema.

Studies measuring neutrophil elastase-like activity in BAL have been generally disappointing. Although values of elastolytic activity in BAL are higher in smokers than non-smokers [294,295], this may be a transient effect of acute smoking [296]. Others have demonstrated low elastase-like activity, which was increased in BAL in patients with emphysema [297]. However, this elastolytic activity does not appear to be due to neutrophil elastase, suggesting that either protease 3 or cathepsin G may be responsible.

### Decreased antiprotease function

A critical event in the protease–antiprotease theory of the pathogenesis of emphysema is the concept of a functional deficiency of  $\alpha_1$ -AT in the airspaces produced by smoking due to oxidation of the methionine-358 residue at the active site of the  $\alpha_1$ -AT molecule. This can occur by a direct oxidative effect of cigarette smoke or by oxidants released

from activated airspace leucocytes [298,299]. A decrease in  $\alpha_1$ -AT function has been confirmed in the lungs in animal models [300] and in at least one study in the lungs of healthy smokers [301]. In addition to the direct oxidant effect of cigarette smoke, both macrophages [302] and neutrophils [303] from cigarette smokers release more reactive oxygen species than cells obtained from non-smokers, and can inactivate  $\alpha_1$ -AT *in vitro* [302]. However, measurements of  $\alpha_1$ -AT in BAL from cigarette smokers indicate that  $\alpha_1$ -AT remains active in smokers [304]; indeed most studies comparing  $\alpha_1$ -AT function in BAL from healthy smokers and non-smokers have failed to find any difference [305,306], although it has been hypothesized that this may be due to mixing of the protein over wide areas in the lungs. Thus there is controversy as to whether the antielastase inhibitory activity of BAL is decreased in smokers, some workers finding it to be fully functional [307,308] and others finding it to be inactivated [305,306,309]. Although Gadek *et al.*'s original study in 1979 [310] showed a reduction in antitrypsin function by 40% in cigarette smokers and later studies revealed the presence of oxidized  $\alpha_1$ -AT in lungs of healthy smokers [301], more recent studies using specific monoclonal antibodies have failed to detect significant amounts of oxidized  $\alpha_1$ -AT in BAL fluid from smokers [311].

Thus studies on the elastase–antielastase imbalance in BAL have failed to produce clear supportive evidence in humans for the protease–antiprotease theory; in particular there is no strong evidence for an imbalance between elastase and  $\alpha_1$ -AT in cigarette smokers. Furthermore, the question of susceptibility of some cigarette smokers to the development of emphysema has not been fully addressed. Several explanations have been proffered to explain this somewhat unclear picture:

- 1 other antielastases may contribute to the antiprotease shield in the lungs, in addition to  $\alpha_1$ -AT;
- 2 more subtle mechanisms may reduce the inhibitory activity of  $\alpha_1$ -AT;
- 3 the protease–antiprotease imbalance occurs in a microenvironment or the lung interstitium, which is not sampled by BAL.

### Other antiproteases

There is considerable controversy regarding the role of other antiproteases in the pathogenesis of emphysema. This controversy is probably related to the techniques that have been used to address this problem. The simplest technique to assess the relative importance of different antiproteases is to compare the inhibitory ability of lung lavage fluid in the presence of known inhibitors. However, several antiproteases inhibit the same enzymes and thus the profile of individual antiproteases has to be assessed against a panel of enzymes in order to distin-

guish the extent of antiprotease activity related to a single antiprotease. This has led to the suggestion by some workers that less than 50% of the inhibition of neutrophil elastase in BAL fluid can be attributed to  $\alpha_1$ -AT [309,312], whereas others using different techniques suggest that  $\alpha_1$ -AT accounts for 90% of the antielastolytic activity in BAL [262].

Antileucoprotease (ALP) is an 11–12 kDa non-glycosylated protein present in lung and a variety of other body secretions. It is an important reversible inhibitor of several serine proteases [313] and is found in mucus, including that in the nose, lung and reproductive tract [314,315]. It is present in high concentrations in bronchial secretions, where it exceeds the concentration of  $\alpha_1$ -AT [316], and has also been shown to be present in Clara cells and peripheral airways [317], although it is present in lesser concentrations than  $\alpha_1$ -AT in BAL fluid [318]. At the bronchial level, ALP has been localized in the non-ciliated cells of the epithelium and the serous cells of the submucosal glands. In bronchioles ALP-producing cells have been identified as Clara and goblet cells [319]. Immunochemical quantification of ALP relative to  $\alpha_1$ -AT shows that the ALP/ $\alpha_1$ -AT molar ratio is approximately 0.1 in the peripheral airspaces [312,318]. In contrast the concentration of ALP in tracheobronchial secretions is three times greater than that of  $\alpha_1$ -AT. This suggests that ALP is a major inhibitor of neutrophil elastase in the large conducting airways. Immunohistological techniques indicate that ALP is present in the alveolar wall of human lungs and, interestingly, is localized in association with elastin fibres [320]. Thus although there is a lower concentration of ALP than  $\alpha_1$ -AT in the peripheral airspaces, its localization in association with elastin, the fact that it is more effective than  $\alpha_1$ -AT at inhibiting neutrophil elastase already bound to elastin [321], that it has been shown to limit connective tissue destruction by adherent neutrophils [322] and that it may be more effective *in vivo* at inhibiting elastase locally in lung tissue all suggest that a major physiological role of ALP may be to inhibit elastin-bound elastase. This is in contrast to  $\alpha_1$ -AT, which inhibits elastase in solutions. Although these immunohistological studies suggest that ALP is an important inhibitor of neutrophil elastase, there is no evidence of a quantitative, functional or absolute deficiency of ALP in patients with emphysema. However, patients with  $\alpha_1$ -AT deficiency and emphysema have low concentrations in the sputum compared with patients with normal  $\alpha_1$ -AT levels [316].

The role of other antiproteases in the pathogenesis of emphysema in smokers is also unclear. An elastase-specific inhibitor called elafin has recently been isolated from bronchial secretions [323] and a low-affinity inhibitor of neutrophil elastase of similar size to ALP has also been demonstrated [316]. The role of these and other inhibitors, such as metalloprotease inhibitors [324] and cysteine

protease inhibitors (cystatins) [325], remain to be elucidated.

#### *Other mechanisms that reduce the effectiveness of antiproteases*

The inhibitory activity of  $\alpha_1$ -AT, as described above, is affected by oxidation. Additional mechanisms that reduce the activity of  $\alpha_1$ -AT include cleavage of the active site and complex formation with the enzyme. Both of these mechanisms produce a change in the molecular size of  $\alpha_1$ -AT; molecules of  $\alpha_1$ -AT with different molecular weights have been shown to be present in BAL from both normal subjects [309] and patients with emphysema [326]. Other subtle changes can occur in the activity of  $\alpha_1$ -AT in smokers, such as a reduction in the association rate constant of  $\alpha_1$ -AT from BAL for neutrophil elastase [327]. Similar changes in association rate constants are found in PiZZ individuals [328].

Although BAL studies do not indicate an absolute or a relative functional deficiency in  $\alpha_1$ -AT in cigarette smokers, it has been suggested that susceptible smokers do not increase their  $\alpha_1$ -AT levels appropriately during the acute-phase response to infection. Recent studies have shown a polymorphism in the  $\alpha_1$ -AT gene [329]. This polymorphism is due to a single change in the nucleotide sequence of the gene, which alters the recognition sequence for the restriction enzyme *TaqI*, thus producing failure of the enzyme to cleave DNA at this site. The area involved in this polymorphism has recently been shown to be an enhancer sequence that can amplify gene expression [330]. Thus the hypothesis is that patients with this polymorphism may not be able to mount an acute-phase response because of the failure of the enhancer sequence to increase gene expression.

#### *Protease–antiprotease imbalance in a microenvironment in the lungs*

A further explanation for the failure to conclusively demonstrate a protease–antiprotease imbalance in the BAL of smokers is that this imbalance occurs in a microenvironment in the lungs not sampled adequately by BAL. Support for this theory comes from studies which show that neutrophils have the ability to degrade connective tissue matrices even in the presence of active enzyme inhibitors [331]. This is thought to result from tight cell adherence to connective tissue substrates and release of the enzyme at the interface between the two, thus excluding surrounding inhibitors. This mechanism clearly cannot be absolute, since it should result in connective tissue degradation in all subjects who have neutrophil recruitment to the lungs. Although there is no direct evidence for this mechanism *in vivo*, neutrophil elastase can

degrade connective tissue *in vitro*, even in the presence of  $\alpha_1$ -AT [321]. Thus the neutrophil has the potential to degrade elastin in a microenvironment, both when sequestered in the microcirculation, during migration through the lung interstitium, or in the airspaces. It has been suggested that the proteolytic imbalance responsible for emphysema may even be derived from neutrophils delayed in the microvasculature by cigarette smoke [332]. These neutrophils may be triggered to release reactive oxygen species that inactivate  $\alpha_1$ -Pi and allow proteolytic enzymes to diffuse the short distance from the neutrophil to elastin and collagen in the alveolar wall. Some support for this hypothesis comes from the marked decrease in the antioxidant capacity of the plasma that occurs during acute cigarette smoking [333]. This increased oxidant stress in the intravascular space could increase the sequestration and adhesion of neutrophils in the pulmonary microvasculature and in addition enhance the inactivation of  $\alpha_1$ -AT.

### Decreased elastin resynthesis

Immunologically reactive elastase, which can be measured in plasma and BAL fluid, is usually in an inactive form complexed with inhibitors. In order to determine the activity of the released enzyme rather than its amount, techniques have been developed to measure functional elastolytic activity in body fluids and to use these measurements to determine susceptibility in populations of smokers or patients with COPD.

Several studies have attempted to measure products of elastin degradation as a reflection of the excess proteolytic activity which is thought to occur in emphysema. The concentrations of the elastin cross-linking peptide desmosine and elastin peptides are elevated in experimental emphysema [334], in smokers and in patients with COPD [335]. The impact of these results is diminished by the fact that elevation of these degradation products is not specific for elastin degradation in the lungs, particularly as the turnover of lung elastin is likely to be very slow [336], and therefore measurements of the levels of these products should be minimal in normal individuals. In fact there is a high background level for the excretion of desmosine in normal non-smokers and this may mask the small changes that may be observed in smokers [337]. Thus no difference has been detected between urinary desmosine measurements in normal adults and those with  $\alpha_1$ -AT deficiency and emphysema or in asymptomatic adults with the PiZZ phenotype [338]. However, a recent study in a small group of smokers demonstrated that urinary desmosine levels were 36% greater in those smokers with a rapid decline in FEV<sub>1</sub> (91±27 mL/year) compared to those with a slow decline in FEV<sub>1</sub> (7±25 mL/year) [339].

Fibrinogen degradation products can be measured as an assessment of the activity of released elastase. The assay is

based on the fact that neutrophil elastase cleaves fibrinogen at the 21–22 amino-terminal sequence of the A $\alpha$  chain to generate an A $\alpha$  1–21 peptide, which would therefore be a specific indicator of elastase activity. Although early studies suggested that this peptide was elevated in both smokers [340] and patients with  $\alpha_1$ -AT deficiency [341], doubts over the suitability of A $\alpha$  1–21 as a marker of elastase activity have been voiced since the peptide is very labile and rapidly degrades to A $\alpha$  1–19 [342]. Furthermore, studies of the relationship between plasma or serum elastin-derived peptides and emphysema, as measured by CT, has produced conflicting results [343,344].

It has been suggested that a further factor leading to the development of emphysema is a defect in elastin resynthesis. Lysyl oxidase is an enzyme required for the cross-linking of elastin fibres and so is necessary for the formation of normal tissue elastin. Emphysema has been described in the connective tissue disorder cutis laxa, which may be partly due to a defect in lysyl oxidase activity [345]. Lathyrogens, which prevent elastin cross-linking, can be used to produce experimental emphysema [346]. There is some evidence to suggest that lysyl oxidase activity is reduced by cigarette smoking and this may contribute to emphysema by preventing elastase repair [347].

## Pathophysiology

### Lung mechanics

The characteristic physiological abnormality in COPD is a decrease in maximum expiratory flow. The concept of the 'equal pressure point' was developed by Mead and colleagues [348], who suggested that during forced expiration an equal pressure point develops in the airways, where the airway pressure becomes equal to the pleural pressure. The pressure driving flow from the alveoli to these equal pressure points is approximately the same as the static recoil pressure of the lungs. Thus three major factors can reduce forced expiratory flow: (i) loss of lung elasticity; (ii) an increase in airways resistance upstream from the equal pressure points; and (iii) an increase in the compliance of the airways downstream from the equal pressure points. When discussing lung mechanics it is useful to relate changes in patients with stable COPD to the stages of the disease, whether mild, moderate or severe. A review of the changes in lung mechanics in acute-on-chronic respiratory failure are described in detail elsewhere [349].

### Mild COPD

The enormous total cross-sectional area of the peripheral airways available for airflow means that the small peripheral airways, which are 2–3 mm or less in diameter, contribute relatively little to the total airways resistance in healthy subjects [171]. Amongst the earliest pathological

changes in cigarette smokers are those in the small bronchi and bronchioles and thus tests have been developed to study function in these peripheral airways. In advanced COPD, peripheral airways are the major site of the increase in total airways resistance. However, in the early stages of the disease, considerable obstructive changes can occur in the peripheral airways without causing significant changes in total airways resistance or maximum expiratory flow [350]. In its early stages the airspace enlargement characteristic of emphysema also has little effect on lung function.

In healthy young subjects, significant airway closure only occurs below functional residual capacity (FRC) [351]. However, enhanced airway closure occurs in the early stage of COPD and this can be measured by plotting nitrogen concentrations against expired volume following a single vital capacity (VC) breath of 100% oxygen. The 'closing volume' measures the lung volume at which expired nitrogen concentrations increase abruptly during slow deflation from total lung capacity (TLC). The closing volume is determined by the lung volume at which some lung units close their airways and hence stop emptying. In healthy young non-smokers, closing volume is about 5–10% of VC. This rises to 25–35% of VC in old age. Compared with non-smokers, young asymptomatic adult smokers have an increase in closing volume. As airways disease progresses the ability to define a closing volume decreases and therefore the test is not useful in established disease. However, follow-up studies of asymptomatic smokers over 10 years indicate that those who eventually develop a reduced  $FEV_1$  initially had an abnormal single-breath nitrogen test. Conversely, many subjects who had an abnormal single-breath nitrogen test did not develop an abnormal  $FEV_1$  over that period [352–354]. The slope of the plot of expired nitrogen concentration against expired volume is also a reflection of early disease, the greater the slope the more uneven being the distribution of ventilation and the more asynchronous the emptying of the lungs.

In comparison to healthy non-smokers, asymptomatic smokers also show frequency dependence of lung compliance, implying increased inequality of time constants in the lungs, resulting from changes in the compliance and resistance of parallel lung compartments [355]. Since the earliest pathological changes in COPD occur in the peripheral airways, it has been suggested that this might be reflected in changes in maximum flow at low lung volumes, below 50% of VC. The normal density dependence of maximum flow at 50% of VC ( $\dot{V}_{max_{50}}$ ) is decreased in some asymptomatic smokers, suggesting a greater contribution of density-independent flow regimes due to laminar flow, presumably in peripheral airways. However, some patients with established COPD retain a normal  $\dot{V}_{max_{50}}$ , possibly because the site of flow limitation remains in the large airways [356]. In addition the lack of a

relation between change in  $\dot{V}_{max_{50}}$  breathing air and helium and pathological changes in the peripheral airway [218,357] has meant that these tests are not in widespread use as a method of detecting mild COPD.

Asymptomatic smokers may show a small reduction in  $K_{co}$  [141]. There is a relationship between measurements of microscopic emphysema and  $K_{co}$ , although emphysema does not explain all the variation in  $K_{co}$  in this relationship [154].

### Moderate to severe COPD

With the development of symptoms of breathlessness, tests of overall lung mechanics such as  $FEV_1$  and airways resistance become abnormal in patients with COPD. These are usually associated with an increase in residual volume (RV) and FRC and in some cases an increase in TLC. Maximum expiratory flow–volume curves show a characteristic convexity towards the volume axis, with (initially) preservation of peak expiratory flow (PEF) and the greatest reductions in expiratory flow at lower lung volumes close to RV (Fig. 23.11).

The uneven distribution of ventilation in advanced COPD causes a reduction in 'ventilated' lung volume and thus  $TLCO$  is almost always reduced, although  $K_{co}$  may remain relatively well preserved in those without emphysema.

The characteristic changes in the static pressure–volume curve of the lungs in COPD are an increase in static compliance and a reduction in static transpulmonary pressure ( $P_L$ ) at a standard lung volume (Fig. 23.12). These changes are generally thought to indicate emphysema. The lung pressure–volume curve can be fitted to a single exponential according to the equation:

**Fig. 23.11** Maximum flow–volume curves in a healthy subject (forced expiratory volume in 1 s,  $FEV_1$ , 2.4 L) and a subject with chronic obstructive pulmonary disease (COPD) and airways obstruction ( $FEV_1$  0.8 L). The development of convexity of the expiratory curve in mild obstruction is characteristic, as is the relative preservation of peak expiratory flow in the patient with COPD.

**Fig. 23.12** Static expiratory pressure–volume curves of lungs in a subject with severe emphysema compared with a normal subject. The broken lines represent extrapolation of the curve to infinite pressure and to the volume axis at zero pressure. (From Gibson *et al.* [359] with permission.)

$$V = V_{\max} - Ae^{-kp}$$

where  $V_{\max}$  represents the theoretical ‘maximal lung volume’ at infinite pressure,  $A$  is the volume difference between  $V_{\max}$  and the volume at zero  $P_L$ , and  $k$  the shape factor that describes the curve and has the dimension  $\text{cm} \cdot \text{H}_2\text{O}^{-1}$ . The constant  $k$  is useful since it describes the shape of the curve independent of the absolute volume of the lung. The shape factor  $k$  rises with increasing age [358,359]. Colebatch and coworkers [358] found a good relationship between an increase in  $k$  and the presence of relatively severe emphysema, measured in postmortem lungs. Similar, but rather weak relationships have been shown between  $k$  or  $P_L$  at 90% of TLC ( $P_{L_{90}}$ ) and macroscopic emphysema in surgical or postmortem lungs [360], and between abnormalities in the pressure–volume curve and the mean number of alveolar attachments to small airways [217,233].

It appears that areas of the lung affected by severe macroscopic emphysema, such as bullae, may not change lung volume at all during a VC manoeuvre and therefore contribute to the static pressure–volume curve only by displacing it to larger absolute volumes. An extension of this hypothesis is that changes in the pressure–volume curve in emphysema are less influenced by localized macroscopic emphysematous changes than by changes in the overall microscopic airspace enlargement, which accompanies and may precede the macroscopic changes. Kim and coworkers [199] used a microscopic scoring system to characterize emphysema into its centriacinar and panacinar forms. In the centriacinar form the distal airspace enlargement occurs around the respiratory bron-

chioles and in the alveolar ducts of the primary lobule, whereas in the panacinar form all the airspaces are enlarged. When they assessed microscopic emphysema as  $L_m$  (p. 631), the mean value for both types of emphysema was not different; however, those with centriacinar emphysema had a significantly increased SD, whereas those with the panacinar type had a narrow SD, indicating uniformly increased alveolar size. However, despite similar mean values of  $L_m$ , those with panacinar emphysema had a greater loss of lung elastic recoil (increased lung compliance, increased  $k$  and decreased  $P_{L_{90}}$ ) than those with centriacinar emphysema. They concluded that the pressure–volume curve in the lung was influenced more by the distribution of alveolar destruction, i.e. using the Swiss cheese analogy, by the ‘cheese’, rather than by the ‘holes’. Support for this contention comes from a study showing a correlation between pressure–volume variables and CT-derived measurements of lung density as an assessment of distal airspace size [361]. In established COPD the evolution of the changes in the pressure–volume curves are not known; however, studies in patients with homozygous  $\alpha_1$ -AT deficiency confirm that considerable change in the pressure–volume curve can occur at an early stage in the absence of airflow limitation.

The results of studies of pulmonary mechanics seem to indicate that the major site of the fixed airway narrowing in COPD is in the peripheral airways less than 2–3 mm in diameter. In addition, loss of lung elastic recoil pressure is also important in terms of airways obstruction, particularly in those with severe emphysema, as a result of a reduction in the distending force on all of the intrathoracic airways. Dynamic expiratory compression of the airways

is enhanced by loss of lung recoil and by atrophic changes in the airways and loss of support from the surrounding alveolar walls, allowing flow limitation at lower driving pressures and flows.

### Pulmonary gas exchange

The underlying structural abnormalities in COPD result in disturbance of pulmonary gas exchange. Ventilation-perfusion ( $\dot{V}_A/\dot{Q}$ ) mismatching is the most important cause of impaired pulmonary gas exchange in COPD. Other causes, such as alveolar hypoventilation, impaired alveolar-capillary diffusion of oxygen and increased shunt, are of much less importance. The distribution of ventilation is very uneven in patients with COPD. A reduction of blood flow is produced by several mechanisms, including local destruction of vessels in alveolar walls as a result of emphysema, hypoxic vasoconstriction in areas of severe alveolar hypoxaemia and passive vascular obstruction as a result of increased alveolar pressure and distension.

The use of the multiple inert gas technique has shown various abnormalities in  $\dot{V}_A/\dot{Q}$  in patients with moderately severe COPD. In most patients the normal unimodal distribution of ventilation-perfusion is disturbed and a bimodal distribution is present. This bimodal distribution takes the form of distinct patterns [362] (Fig. 23.13). In the first pattern a substantial amount of ventilation is distributed to regions of high  $\dot{V}_A/\dot{Q}$  ratios, thus enlarging the physiological dead space. The second pattern is characterized by lung units where a large proportion of blood flow is diverted to areas with low  $\dot{V}_A/\dot{Q}$  ratios [362,363], although a true increase in anatomical shunt is unusual except in severe exacerbations of COPD, particularly those requiring assisted ventilation [364]. Thus in spite of severe unevenness of ventilation and even occlusion of many

peripheral airways, significant ventilation is still present in most areas of perfused lung, suggesting that collateral ventilation occurs. This is enhanced by lung distension in the presence of emphysema, where collateral channels are an important pathway for ventilation [365]. The third pattern is a combination of the first two.

Although a reduced  $TLCO$  is almost universal in advanced cases of COPD, analysis by the multiple gas technique does not suggest any significant alveolar-end-capillary limitation for oxygen at rest or during exercise, and that  $\dot{V}_A/\dot{Q}$  mismatching accounts for all of the hypoxia observed in these patients [362].

Patients with COPD have been divided on clinical grounds and blood gas abnormalities into two extreme presentations. Type A patients or 'pink puffers' have severe dyspnoea, a normal or low  $Paco_2$ , only a mild decrease in  $Pao_2$  at rest, and a low  $DLCO$ . These patients are hypoxaemic only at a late stage in the disease and therefore do not develop pulmonary hypertension, cor pulmonale and consequently fluid retention and secondary polycythaemia. In contrast, 'blue bloaters' or type B patients present with cough and sputum production and are likely to develop hypoxaemia and hypercapnia earlier in the course of their disease, and hence cor pulmonale, fluid retention and polycythaemia. The 'pink puffers' were thought to have predominantly emphysema and the 'blue bloaters' were the bronchitic type as described by Burrows and colleagues [366]. These types of presentation appear to represent two ends of a clinical spectrum in which most patients cannot be distinguished so clearly. However, Wagner and coworkers [367] in the late 1970s showed in 23 stable patients with advanced COPD that the majority of patients classified as 'pink puffers' had high  $\dot{V}_A/\dot{Q}$  patterns, whereas those characterized as 'blue bloaters' had no consistent pattern of  $\dot{V}_A/\dot{Q}$  ratios. They also found no

**Fig. 23.13**  $\dot{V}_A/\dot{Q}$  distributions in patients with advanced chronic obstructive pulmonary disease. Type H (high) represents a pattern where a substantial amount of ventilation is distributed to high  $\dot{V}_A/\dot{Q}$  regions; type L (low) depicts a profile where a marked amount of blood flow is diverted to low  $\dot{V}_A/\dot{Q}$  regions;

type HL is a mixture of both abnormal  $\dot{V}_A/\dot{Q}$  patterns. Shunt (left closed symbol) is trivial in all cases, whereas dead space (open symbol with arrow) is always moderately increased in all three patterns. (From Rodriguez-Roisin *et al.* [369] with permission.)

correlation between spirometry and the respiratory blood gases or  $\dot{V}_A/\dot{Q}$  ratio distributions in these patients [367]. These findings have been confirmed by others [368].

The blood gas abnormalities that occur during exacerbations of COPD may take several weeks to improve after treatment [369]. A study of sequential measurements in patients presenting with acute hypercapnic respiratory failure and COPD, but not requiring mechanical ventilation, showed that the severity of all the gas-exchange indices had improved after 1 month, with an increase in  $P_{aO_2}$  and a decrease in  $P_{aCO_2}$ . Indeed some of the distributions of  $\dot{V}_A/\dot{Q}$  inequalities had become unimodal [369]. These data suggest that some of the  $\dot{V}_A/\dot{Q}$  abnormalities occurring during exacerbations of COPD are due to partially reversible pathophysiological changes such as inflammation, producing airway narrowing and mucous plugging. Studies in patients with COPD requiring mechanical ventilation show that the patterns of  $\dot{V}_A/\dot{Q}$  abnormalities are more severe than those in patients breathing spontaneously [364]. The main difference between the stable group and the severe exacerbation/ventilated group is the presence of an intrapulmonary shunt of around 4–10% of cardiac output. This suggests that there is complete occlusion of some airways, possibly by bronchial secretions.

In severe but stable COPD, the patterns of  $\dot{V}_A/\dot{Q}$  distributions do not change on exercise [367] and may show a modest improvement in less severely disabled patients [368]. Barbera and coworkers [368] studied a group of 23 patients with a mild obstructive ventilatory pattern ( $FEV_1$  76% of predicted). The majority of these patients had a normal  $TLCO$ . The  $P_{aO_2}$  and  $P_{aCO_2}$  were also normal and the mean alveolar–arterial  $P_{O_2}$  gradient was moderately increased ( $>2$  kPa, 15 mmHg). These patients had only mild abnormalities in the dispersion of ventilation and blood flow, there was no evidence of an increase in shunt and the dead space was normal. Blood flow distributions were unimodal in two-thirds of patients and bimodal in the remaining one-third. In contrast, the ventilation distributions were never bimodal and therefore there were no areas of very high  $\dot{V}_A/\dot{Q}$  ratios. Preliminary studies suggest that functional abnormalities in small airways can produce maldistributions of ventilation and hence  $\dot{V}_A/\dot{Q}$  mismatching in the face of a normal  $P_{aO_2}$  [370].

There is a broad relationship between spirometry and blood gases in patients with COPD, where  $P_{aCO_2}$  rises when the  $FEV_1$  falls below 1.5 L [371]. This relationship also shows that although most patients whose  $FEV_1$  is less than 1 L have some degree of hypercapnia, many patients have normal  $P_{aCO_2}$  with very severe degrees of airways obstruction.

## Respiratory muscles

In patients with severe COPD a combination of pul-

monary overinflation and malnutrition, resulting in muscle weakness, reduces the capacity of the respiratory muscles to generate pressure over the range of tidal breathing. In addition, the load against which the respiratory muscles need to act is increased because of the increase in airways resistance. Overinflation of the lungs leads to shortening and flattening of the diaphragm, thus impairing its ability to generate pressure in order to lower pleural pressure. During quiet tidal breathing in normal subjects, inspiration is achieved predominantly by contraction of the diaphragm and expiration is largely passive, and depends on the elastic recoil of the lungs and the chest wall. As a result, patients with COPD need increasingly to use their rib cage muscles and inspiratory accessory muscles, such as the sternomastoid, even during quiet breathing. During exercise, this pattern may be even more distorted and on occasions results in paradoxical motion of the rib cage. Surprisingly, although the airway narrowing worsens on expiration in COPD, the respiratory muscles have most problems on inspiration.

The respiratory muscles show some morphological abnormalities in patients with COPD that could theoretically contribute to muscular weakness. Although the proportions of type I fibres (slow-contracting) and type II fibres (fast-contracting: type IIA fatigue resistant; type IIB fatiguable) are similar in normal subjects and in patients with COPD, subtle changes are present in these patients, such as a decrease in the diameter of individual fibres, variations in fibre size and splitting of fibres [372]. In addition, in autopsy studies of patients with severe COPD, the diaphragm, the main inspiratory muscle, is reduced in weight greater than would be expected for the reduction in overall body weight in these patients [373]. The metabolic activity of the diaphragm in patients with COPD is less than in normal subjects [374]. This argues against any training effect in response to the chronic increased work in patients with COPD. In addition the respiratory muscles in patients with COPD show decreased levels of ATP, which is necessary for muscle contraction [375]. This, together with the effects of hypercapnia, hypoxaemia, electrolyte and mineral deficiencies and infection, may contribute to the generalized muscle weakness in patients with severe COPD.

Weight loss is a common feature in patients with advanced COPD, in spite of a normal or increased dietary intake. Together with the increased metabolic requirements of the respiratory muscles as a result of the increased work of breathing, this produces an abnormally high resting energy expenditure in these patients [376]. The presence of these abnormalities has led to attempts to improve nutrition and hence respiratory muscle function in patients with COPD.

Clinical assessment of the global function of the respiratory muscles is often performed by measuring maximum inspiratory and expiratory mouth pressures ( $P_{imax}$ ,

$P_{Emax}$ ). Patients with COPD have impaired values of  $P_{imax}$  [377], although these measurements are very effort dependent. Diaphragmatic function can be assessed during inspiration by measurement of transdiaphragmatic pressure ( $P_{di}$ ) using balloon-tipped catheters or small transducers placed in the oesophagus and stomach. Measurements of  $P_{di}$  are also reduced in patients with COPD [378]. However, there is evidence that diaphragmatic function remains well preserved, at least in well-nourished patients with COPD [379], probably as a result of adaptation to overinflation via a mechanism that has not as yet been fully elucidated [379].

In patients with COPD and severe airways obstruction, expiratory airflow limitation occurs even during tidal breathing. This has led to the concept of 'dynamic hyperinflation' where expiration ends at a lung volume above FRC; as a consequence, inspiratory muscle contraction for the next inspiration occurs before expiratory flow ceases. This increases the burden on the inspiratory muscles as a result of an increase in elastic load associated with tidal breathing over a higher volume range. Thus the inspiratory muscles have to overcome what has been termed 'intrinsic positive end-expiratory pressure' before inspiration and hence lung inflation can commence.

### Respiratory muscle fatigue

Respiratory muscle fatigue is defined as a loss of the capacity of the muscles to develop force and/or velocity, resulting from muscle activity under load, that is reversible by rest [380]. The fact that it is reversible by rest distinguishes fatigue from muscle weakness. Numerous studies have explored the hypothesis that respiratory failure in patients with COPD is due to respiratory muscle fatigue [381]. Despite extensive investigation using various methods of assessment, including response to electrical stimulation, analysis of electromyographic spectra and analysis of the relaxation rate of the diaphragm, the evidence for respiratory muscle fatigue in experimental studies in patients with COPD during normal breathing is still a matter of debate [382,383].

The principle of the fatigue threshold for a muscle that contracts intermittently, such as the diaphragm, depends on the tension developed and the duration of each contraction. Thus diaphragmatic fatigue has been assessed by calculation of the tension–time index, which is the product of the mean  $P_{di}$  (as a fraction of  $P_{dimax}$ ) and the proportion of each breathing cycle spent on inspiration, i.e. the time during which the diaphragm is contracting (the so-called 'duty cycle') [384]. At rest, fatigue is considered to occur when the tension–time index is in the range 0.15–0.20. Since the mean  $P_{di}$  during a breath is increased in patients with COPD whereas the  $P_{dimax}$  decreases, this means that a threefold increase in  $P_{di}$  would be sufficient to push the tension–time index into the range at which

fatigue is likely to occur, in comparison to the eightfold increase that would be necessary in a normal subject [385]. Although patients with COPD have a higher tension–time index than normal subjects, the value does not lie within the fatiguing range [385]. Although hypercapnic patients with COPD have a higher tension–time index than those who are normocapnic [386], the tension–time index does not exceed the fatigue threshold, even in those who have severe hypercapnia [387].

### Breathing adaptations in patients with COPD

As a result of the respiratory muscle dysfunction in patients with COPD, patients with severe disease adopt a characteristic breathing pattern during tidal breathing, consisting of rapid frequency and a small tidal volume. This pattern helps to avoid the development of respiratory muscle fatigue but predisposes patients to the development of hypercapnia [386]. In contrast to normal subjects, who during quiet tidal breathing have predominantly abdominal breathing, patients with COPD, due to the presence of overinflation, demonstrate a relative increase in the motion of the rib cage and a decrease in diaphragmatic movement [388].

The increase in anteroposterior diameter of the rib cage, the classical clinical sign of overinflation, does not appear to be due to an absolute increase in the anteroposterior diameter of the chest, since radiographic measurements in patients with COPD have shown that both the anteroposterior diameter and the angulation of the ribs in patients with COPD are similar, at the same absolute lung volumes, to those in normal subjects of a similar age [389]. This clinical sign is therefore probably due to the increased resting lung volume of such patients. Indrawing of the lateral rib-cage margin occurs in some patients with COPD on inspiration (Hoover's sign) and paradoxical inspiratory motion of the abdomen and lower sternum also occurs as a result of overinflation [386]. The characteristic posture that many patients with severe airway obstruction adopt, leaning forward with outstretched arms in support, is a further adaptation which improves the maximum inspiratory pressure ( $P_{imax}$ ) [390], probably by improving the length–tension characteristics of the diaphragm and thereby allowing it to generate more force more effectively, accompanied by a reduction in the activity of the inspiratory accessory muscles.

### Therapeutic interventions

#### Respiratory muscle training

Benefits in specific respiratory muscle function tests can be achieved with respiratory muscle training. Although improvements in respiratory muscle function tests can be demonstrated, there is no consistent improvement in

exercise performance in these studies. Indeed a meta-analysis of 17 randomized trials of respiratory muscle training in patients with COPD showed that although training, using either resistance breathing or isocapnic hyperventilation, improved respiratory muscle strength and endurance, there was no overall improvement in exercise tolerance [391].

### Drug therapy

Numerous *in vitro* studies have shown that methylxanthines such as theophyllines (in doses not possible in humans) potentiate the response of fresh and fatigued muscle strips to an electrical stimulus. The results *in vivo* in humans have been less convincing and have either reported small or no improvements in the  $P_{di}$  generated during maximal voluntary effort [392,393].

### Ventilatory support

Some uncontrolled studies have suggested that resting the respiratory muscles, by long-term nocturnal use of either negative pressure applied to the chest wall or intermittent positive pressure ventilation (IPPV) using a nasal mask, results in some improvement in respiratory muscle function. However, a large controlled study failed to show any benefit on respiratory muscle function in patients with COPD [394]. Indeed the increase in negative intra-airway pressures generated by negative pressure ventilation may result in obstructive sleep apnoea in a few patients [395]. The use of nasal IPPV has been supported by uncontrolled studies that suggest benefit [396,397], but larger controlled studies are required before this form of treatment can be recommended in patients with chronic stable COPD.

### Nutritional supplementation

The results of controlled trials on the effects of nutritional supplementation on respiratory muscle function in malnourished patients with COPD have shown no consistent benefit [398–402]. Those studies that have achieved positive results have done so in association with an increase in weight. However, the cost-effectiveness of these studies has to be questioned.

### Control of ventilation

There are three major factors that influence the motor output of the respiratory system: inputs from the chemoreceptors, mechanoreceptor input and cortical factors. These factors all have an influence on ventilation in patients with COPD and their influence can vary depending on the situation. The control of ventilation has always been considered to be deranged in patients with

COPD. However, the techniques for assessing ventilatory control in these patients are fraught with methodological problems. The classical techniques of the steady-state carbon dioxide response during progressive isocapnic hypoxia or hyperoxia and the carbon dioxide rebreathing test are difficult both to perform and interpret in patients with COPD, particularly those who are already hypoxaemic. A simple assessment of minute ventilation indicates that most patients in the stable state, even with severe COPD, have a normal or slightly increased minute ventilation compared with normal subjects [403,404]. Even in those in whom ventilation–perfusion mismatching or an increase in the physiological dead space results in a rise in  $P_{aCO_2}$ , minute ventilation remains in the normal range [403,405]. However, the use of ventilation as a measure of the ventilatory output in COPD is influenced by abnormal lung mechanics.

Measurement of mouth pressure in the first 0.1 s of an occluded inspiration ( $P_{0.1}$ ) is a non-invasive technique that gives an indication of the central drive to breathing [406]. However, in severe airways obstruction, with large swings in intrathoracic pressure, transmission of these swings may be delayed, which therefore reduces the  $P_{0.1}$  measured at the mouth [406]. However, allowing for these limitations, this is probably the best test of ventilatory control in COPD and has been used most often. The only test of ventilatory control not influenced by respiratory mechanics is electromyography of the diaphragm, which is a technically difficult test to perform. However, limited studies using this method suggest that diaphragmatic activity in patients with COPD, particularly in response to hypercapnia, is greater than in normal subjects [407].

Many studies have measured the ventilatory or  $P_{0.1}$  response to breathing carbon dioxide and have demonstrated that the chemoreceptor control of breathing is abnormal in patients with severe COPD [408–410]. There is agreement between these studies that there is a reduced ventilatory response to hypoxia and hypercapnia, which is usually associated with increased neural output compared with normal subjects. It is not clear whether the increased neural output can be explained by the increase in the mechanical load imposed on the respiratory system in COPD or whether this represents an intrinsic reduction in respiratory chemosensitivity. The data available suggest that an increase in the mechanical load on the respiratory system is responsible for the impaired ventilatory response to changes in blood gas tensions [411].

Another controversial issue relates to whether those patients with COPD who develop hypoxia and hypercapnia ('blue bloaters') differ in their responses from those who maintain their blood gases but have similar impairment in  $FEV_1$  ('pink puffers'). Some studies, using various techniques, suggest that hypercapnic patients have a lower respiratory drive to breathing than eucapnic patients [412,413], although this has not been confirmed in

other studies [414]. Methodological problems may have resulted in the apparent discrepancies between these studies. In addition, compensatory changes in cerebrospinal fluid acid–base status, as a result of chronic hypercapnia, may mask any acute changes that stimulate peripheral chemoreceptors and thus makes interpretation of these data difficult [415]. In patients with acute exacerbations of COPD and acute respiratory failure,  $P_{0.1}$  is five times greater than in normal subjects [404].

Support for the hypothesis that differences in hypoxic and hypercapnic drives to breathing account for the different clinical patterns of COPD comes from studies of healthy family members of patients afflicted by COPD. These studies avoid the problems inherent in studying respiratory drive in a patients with lung disease [416,417] and have shown that reduced hypercapnic and hypoxic drives to breathing occur more frequently in individuals whose relatives have developed hypercapnic COPD compared with relatives of those patients with similar degrees of airways obstruction who have not developed hypercapnia. However, larger studies are required to confirm these results.

### **Pulmonary hypertension, cardiac function and fluid balance**

Pulmonary arterial hypertension develops late in the course of COPD, with the development of hypoxaemia ( $P_{aO_2} < 8 \text{ kPa}$ , 60 mmHg) and usually hypercapnia. It is the major cardiovascular complication of COPD and is associated with the development of right ventricular hypertrophy (cor pulmonale) [418] and with a poor prognosis [419].

### **Pulmonary circulation**

Changes in the pulmonary circulation occur characteristically in the peripheral arteries in patients with COPD [228,420]. Among the earliest changes in the pulmonary vasculature that develop as airflow limitation worsens is thickening of the intima of the small pulmonary arteries [420,421]. Medial hypertrophy then develops in the muscular pulmonary arteries in those patients who develop pulmonary arterial hypertension [422]. Peripheral airway inflammation in patients with COPD may be associated with pulmonary arterial thrombosis [223].

When chronic hypoxaemia develops, the consequent pulmonary arterial hypertension is associated with right ventricular hypertrophy. Indeed a relationship has been shown between the usual  $P_{aO_2}$  in a group of patients receiving long-term oxygen therapy and the degree of right ventricular hypertrophy [223]. However, there is no relationship between right ventricular weight and the extent of emphysema in postmortem lungs [423]. Furthermore, the extent of emphysema, as measured by CT, does

**Table 23.4** Factors contributing to the development of pulmonary arterial hypertension in patients with COPD.

Destruction of the pulmonary vascular bed
Abnormal blood gas tensions
Abnormal pulmonary mechanics
Increased cardiac output
Blood volume changes
Increased blood velocity
Endothelial abnormalities

not correlate with the pulmonary arterial pressure in patients with COPD [424].

Several factors contribute to the development of pulmonary arterial hypertension in patients with COPD (Table 23.4). The most important of these factors is alveolar hypoxaemia. Hypoxia is a potent pulmonary vasoconstrictor in normal subjects [425]. Many studies have shown a negative correlation between oxygen saturation and pulmonary arterial pressure in patients with COPD [426]. However, supplemental oxygen therapy produces only a trivial fall in pulmonary arterial pressure, which seldom falls to normal values in these patients due to the presence of structural abnormalities in the pulmonary arteries. A positive correlation has also been shown between  $P_{aCO_2}$  and pulmonary arterial pressure [427].

Although the factors listed in Table 23.4 contribute to its development, the fundamental mechanisms resulting in pulmonary hypertension in patients with hypoxic COPD remain unclear [428]. There is increasing evidence that endothelial dysfunction is an underlying factor. This may result in a reduction in nitric oxide synthesis or release in response to hypoxaemia [429]. Thus the putative role of nitric oxide in preventing an excessive rise in pulmonary vascular tone, as a result of stimuli such as hypoxaemia, may be lost in COPD. Support for this contention comes from studies showing that isolated pulmonary arterial rings from patients undergoing lung transplantation for end-stage COPD have impaired endothelium-dependent vasodilatation [430]. It has also been suggested that nitric oxide may have an inhibitory effect on cell proliferation in the pulmonary vessel walls and therefore has a role in preventing the vascular remodelling that occurs in hypoxic COPD [429].

### **Pulmonary haemodynamics**

Pulmonary haemodynamics in patients with COPD depend on the stage of the disease. In patients with mild COPD, without severe hypoxaemia or hypercapnia, pulmonary arterial pressure is usually normal or only slightly elevated when measured at rest but may rise abnormally during exercise [431–434]. Cardiac output is normal, as are right atrial and right ventricular end-diastolic pressures. The vascular resistance is therefore normal or only slightly

**Table 23.5** Haemodynamics and blood gases in 74 patients with COPD and 32 normal subjects. (From Naeije [436].)

	COPD		Normal	
	Mean	Range	Mean	Range
$P_{aO_2}$ (mmHg)	43	23–67	91	75–105
$P_{aCO_2}$ (mmHg)	51	33–68	38	32–43
Cardiac output (L/min/m <sup>2</sup> )	3.8	2.3–5.8	3.6	2.6–4.5
Right atrial pressure (mmHg)	3	0–21	5	2–9
Mean pulmonary arterial pressure (mmHg)	35	15–78	13	8–20
Pulmonary artery wedge pressure (mmHg)	6	0–19	9	5–14
Pulmonary vascular resistance index (dyne/s/cm <sup>5</sup> /m <sup>2</sup> )	660	231–1377	58	40–200
Right ventricular stroke work index (g/m)	16	5–29	6	3–18

elevated when measured at rest but may rise markedly during exercise [431,433].

As airflow limitation and arterial blood gas abnormalities worsen, particularly when chronic hypoxaemia and hypercapnia are present, pulmonary hypertension develops at rest and worsens on exercise. However, even in patients with severe COPD when measurements are made in a clinically stable state, the pulmonary arterial pressure is only modestly elevated [435] (Table 23.5).

### Effects of pulmonary hypertension

The natural history of untreated pulmonary hypertension in patients with COPD is of slow progression. Weitzenblum and coworkers [436] found a change of greater than 5 mmHg in the mean pulmonary arterial pressure in only 33% of patients with established pulmonary hypertension, measured over a 5-year period. In these patients, hypoxaemia and hypercapnia also progressed. In spite of the slow progression, the presence of pulmonary arterial hypertension implies a poor prognosis. In one study, those who had a normal pulmonary arterial pressure had a 72% 4-year survival compared with a 49% survival in those whose pulmonary arterial pressure was elevated [437]. However, many other factors such as FEV<sub>1</sub> and arterial blood gas values also affect survival in COPD [437–439]. The presence of pulmonary arterial hypertension may therefore simply be a reflection of the severity of the disease and may not have a direct effect on mortality.

Mixed venous  $P_{O_2}$  also correlates with survival in patients with COPD [440]. It has been proposed that patients with COPD who have decreased oxygen carriage maintain a higher cardiac output as an adaptive mechanism to sustain normal tissue oxygenation. Thus failure to maintain an adequate cardiac output may worsen survival [435].

Cor pulmonale was defined by a WHO expert committee [441] as ‘hypertrophy of the right ventricle resulting from diseases affecting the function and/or structure of the lungs, except when these pulmonary alterations are the result of diseases that primarily affect the left side of

the heart, as in congenital heart disease’. This is a pathological definition of limited clinical value since the diagnosis of right ventricular hypertrophy in life is imprecise. The definition was revised by Behnke and colleagues [442] who replaced the term ‘hypertrophy’ by ‘alteration in structure and function of the right ventricle’. However, the definition remains imprecise as it covers a spectrum of dysfunction from mild abnormality to frank right ventricular failure. Indeed the term ‘cor pulmonale’ is often misused as a synonym for right ventricular failure or to indicate the presence of pulmonary hypertension in patients with COPD [443].

The prevalence of right ventricular hypertrophy in a large European study of patients with ‘lung disease’ was 8.9% [444] and increased as airflow limitation worsened in patients with COPD, being present in 70% when the FEV<sub>1</sub> had fallen to 0.6 L [445]. The development of oedema in patients with hypoxic COPD is usually a late feature, often occurring during acute exacerbations of the condition [446]. However, a proportion of patients who develop pulmonary hypertension or indeed right ventricular hypertrophy never develop peripheral oedema [447]. Patients who are free of oedema at first presentation have developed oedema for the first time at a rate of 6% per annum in studies over a 3–4 year follow-up period [448].

### Clinical assessment of pulmonary haemodynamics

The presence of pulmonary hypertension produces accentuation of the pulmonary component of the second heart sound, and a systolic parasternal heave indicates right ventricular hypertrophy. However, these clinical signs are often difficult to detect in patients with COPD because of overinflation of the chest and posterior rotation of the heart [449]. Extra heart sounds and the murmur of tricuspid regurgitation, which are best heard on inspiration, all suggest right ventricular dysfunction but again may be obscured by overinflation; the jugular venous pressure is often difficult to assess due to large swings in intrathoracic pressure. Peripheral oedema may be due to other causes

such as hypoalbuminaemia. These signs develop late in the clinical course in patients with COPD and are not sensitive indicators of pulmonary hypertension or right ventricular hypertrophy.

The presence of pulmonary hypertension can be assumed on a plain chest radiograph if the right descending main pulmonary artery has a width greater than 16 mm [450]. However, in one study the sensitivity for detecting a mean pulmonary arterial pressure of greater than 20 mmHg was only 43%, with a specificity of 63% [451]. In a subgroup of patients with mild pulmonary hypertension (mean pulmonary arterial pressure 20–30 mmHg), the sensitivity was only 38%. Right ventricular hypertrophy or dilatation is not easily recognized on a plain chest radiograph, although encroachment into the retrosternal space on a lateral chest film can be a helpful sign [452].

ECG criteria for detecting right ventricular hypertrophy have a reasonably high specificity of 86 and 96% in two studies but have a relatively low sensitivity (38 and 63% respectively) [451,453].

Detectable tricuspid regurgitation by echo Doppler is probably the best technique to measure pulmonary arterial pressure non-invasively. In this technique the transtricuspid pressure gradient (DP) is calculated from the maximum velocity ( $v$ ) of the tricuspid regurgitant jet, using a simplified form of the Bernoulli equation: DP (mmHg) =  $4 \times v^2$ . Adding the transtricuspid gradient to the mean right atrial pressure (estimated clinically from the jugular veins) allows calculation of the right ventricular systolic pressure. In patients with a wide range of cardiac diseases and hence pulmonary arterial pressures, correlation coefficients between Doppler and cardiac catheter measurements have ranged between 0.89 and 0.97 [454]. A tricuspid regurgitant signal can be recorded in 90–100% of patients with clinical signs of right heart failure and is almost invariably present in those with a pulmonary arterial pressure of greater than 50 mmHg [455]. This falls to 72% in the absence of right heart failure [456] and can be as low as 24% in patients with COPD [457], although the detection rate improves with the use of saline contrast enhancement [458]. The pulsed Doppler technique can be used to record pulmonary artery flow velocity. Measurement from the Doppler pulmonary flow velocity curves of the time to peak flow velocity (or acceleration time), which is reduced in the presence of pulmonary hypertension, correlates significantly but variably with the pulmonary arterial pressure or pulmonary vascular resistance ( $r=0.65-0.96$ ); recovery rates for pulmonary flow velocity curves are high, ranging from 81 to 98% [456,457,459–461].

Two-dimensional and M-mode echocardiography have been used to assess right ventricular dimensions and function [462]. Quantitative techniques are available to assess right ventricular volume by echocardiography but are cumbersome and not used clinically. M-mode echocardiography can be used semi-quantitatively to assess right

ventricular dimensions from a parasternal view. A right ventricular end-diastolic dimension of greater than 25 mm is reasonably predictive of right ventricular enlargement, and a right ventricular wall thickness of more than 6 mm is associated with right ventricular pressure overload in patients with COPD [451]. Pressure overload on the right ventricle also produces right ventricular wall motion abnormalities, which can be qualitatively assessed but accuracy is heavily dependent on the experience of the operator. A characteristic abnormality associated with right ventricular pressure overload on two-dimensional echocardiography is systolic bowing of the interventricular septum towards the left ventricle [463].

There are problems with obtaining a good echocardiographic signal in patients with COPD [454,464], particularly related to overinflation of the lungs, which reduces the window available for the examination. Most studies report that an adequate examination can be obtained in more than 70% of patients, although the range of examinations from which clinically useful information can be obtained varies from 24 to 98% in published studies [451,457].

Right ventricular dimensions are more accurately assessed by magnetic resonance imaging (MRI) [465,466]. Right ventricular wall volume has been shown to correlate with pulmonary arterial pressure [465]. An emerging technology that may prove useful in the evaluation of patients with COPD is ultrafast CT, which can be used to assess ventricular volumes and systolic function [467]. Its role in COPD remains to be established. However the high cost of CT and MRI have limited their availability.

One of the major indications for assessing cardiac function in COPD is to determine the potential role of other cardiovascular diseases that may coexist and may contribute to the patient's symptoms. There is still some debate about whether left ventricular dysfunction contributes to the syndrome of cor pulmonale [468]. Measuring the pulmonary arterial pressure is not a routine test in the assessment of patients with COPD but may become more important if new therapeutic options become available for the treatment of pulmonary hypertension.

### Right ventricular function

The question of whether the right ventricle truly fails in patients with COPD is the subject of much debate [469,470]. The classical view of the development of 'heart failure' in patients with COPD is that hypoxia leads to pulmonary hypertension, which imposes increased work on the right ventricle, leading to right ventricular hypertrophy and eventually right ventricular dilatation and the development of peripheral oedema [471]. Thus the definition of right heart failure in this context is an inability of one or more of the chambers of the heart (the right ventricle in this case) to accept and expel venous return

throughout the range of physiological activity, without alteration of normal circulatory haemodynamics [472]. In such patients, however, the cardiac output remains normal or may even be slightly elevated [433,473].

The problem of assessing right ventricular function is the lack of a good non-invasive method of assessment, because of the wide variability of right ventricular geometry [474]. Radionuclide ventriculography overcomes this problem but may produce a falsely high value for right ventricular ejection fraction in the presence of tricuspid regurgitation. Right ventricular ejection fraction measured using this technique has a wide range of values in a population of patients with COPD but are on average lower than those in a normal population (<40%), particularly in patients who have developed peripheral oedema [475]. Studies using a combination of invasive pulmonary haemodynamics, measured by cardiac catheterization, and radionuclide ventriculography suggest that right ventricular contractility is maintained in patients with COPD when their condition is clinically stable, even in the presence of increased pulmonary arterial pressure [476].

In patients who have developed respiratory failure and peripheral oedema, pulmonary arterial pressure is greater than those studied in a stable state but decreases with treatment [433,473]. However, cardiac output remains normal in these patients compared with the low-output state that occurs in congestive cardiac failure [477]. In patients with oedema, right ventricular contractility is decreased [473], in association with an increase in right ventricular end-diastolic pressure and volume [473,478]. Although this decrease in right ventricular contractility may be related to the level of pulmonary arterial pressure in some patients [478], this has not been confirmed in all studies [473].

### Cause of the oedema

There is increasing evidence that the oedema which develops late in the course of the disease in patients with COPD may not be entirely due to right ventricular failure [479]. A complex balance exists between factors that promote salt and water retention and those that promote natriuresis in patients with COPD. The key factor leading to changes in salt and water balance in patients with COPD is the development of hypoxaemia in association with hypercapnia.

The most consistent change in renal function in patients with hypoxic COPD, particularly those with oedema, is a reduction in renal blood flow [480]. This fall in renal blood flow has recently been confirmed non-invasively by Doppler ultrasound [481]. Hypoxia and hypercapnia may interact to reduce renal blood flow. Hypercapnia reduces renal blood flow through catecholamine release and via a neurally mediated action [482].

In addition, arginine vasopressin (AVP) levels may be inappropriately high in patients with COPD who have

developed both hypoxia and hypercapnia, particularly those who have also developed oedema, and this may also contribute to increased water retention [483]. The mechanism of this increase in AVP is poorly understood but may relate to stimulation of AVP release as a consequence of activation of the renin-angiotensin system [484].

Several studies have now demonstrated changes in hormonal balance in patients with COPD and chronic respiratory failure, including activation of the renin-angiotensin-aldosterone system [483-485] and elevation of circulating catecholamines [484], particularly in those patients who have developed oedema [486,487]. Thus a decrease in renal blood flow, activation of the renin-angiotensin system and increase in AVP as a result of changes in blood gases lead to salt and water retention in patients with COPD. There is also some evidence that sub-clinical autonomic nerve dysfunction, which is relatively common in patients with severe COPD [488], may affect hormonal levels [489] and renal blood flow [490], and may also contribute to the salt and water retention in these patients [491].

However, several compensatory mechanisms that promote natriuresis are also activated in patients with hypoxic COPD [468]. The levels of atrial natriuretic peptide (ANP) are elevated in patients with COPD [492,493], particularly in those with oedema [494]. Increased release of ANP results from increased atrial stretch as a result of the presence of pulmonary hypertension [495]. ANP has a number of potential beneficial effects that could act to prevent the development of oedema in patients with COPD, including the promotion of natriuresis [496], decrease in plasma renin activity [497] and inhibition of angiotensin II-mediated aldosterone production [498]. Moreover, ANP produces pulmonary vasodilatation [496]. A number of other factors, including renal dopamine [499] and digoxin-like immunoreactive factor [500], may also be activated and promote natriuresis.

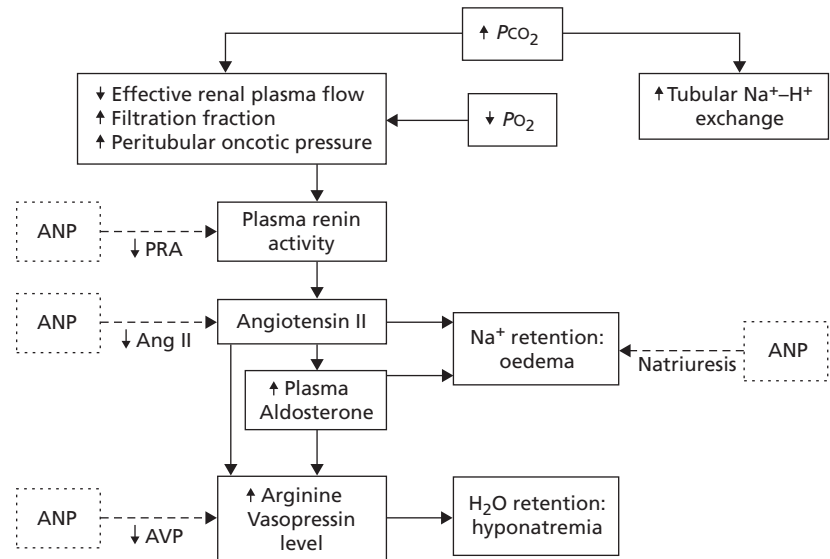

Thus a complex interaction between pulmonary haemodynamics and changes in salt, water and hormonal homeostasis occurs in patients with hypoxic and hypercapnic COPD. The influence of the protective diuretic and natriuretic factors probably prevents the formation of oedema in most patients. However, in some patients these protective mechanisms are overwhelmed by the oedema-promoting factors, such as activation of the renin-angiotensin system, leading to the development of oedema (Fig. 23.14).

## Clinical features

### Symptoms

The characteristic symptoms of COPD are breathlessness on exertion, sometimes accompanied by wheeze and cough, which is often but not invariably productive [501].

**Fig. 23.14** Mechanisms of sodium, water and hormonal disturbance in patients with chronic obstructive pulmonary disease. ANP, atrial natriuretic compound. (Modified from MacNee [468].)

Breathlessness is the symptom that commonly causes the patient to seek medical attention and is usually the most disabling of these symptoms. Patients often date the onset of their illness to an acute exacerbation of cough with sputum production, which leaves them with a degree of chronic breathlessness. However, close questioning usually reveals the presence of a 'smoker's cough', with the production of small amounts (usually  $<60\text{mL}$ ) of mucoid sputum, often occurring predominantly in the morning for many years [24].

Most patients have a smoking history of at least 20 pack-years before symptoms develop, commonly in the fifth decade, although dyspnoea on effort often does not occur until the sixth or seventh decades. It is characteristic of COPD that patients progress through the clinical stages of mild, moderate and severe disease. Symptoms and signs therefore vary in any individual depending on the stage of the disease.

Breathlessness is the symptom that causes most disability and is associated with loss of lung function over time [28]. It is usually first noticed on climbing hills or stairs, while carrying heavy loads or hurrying on level ground. The appearance of breathlessness indicates moderate to severe impairment of airway function. By the time the patient seeks medical advice the  $\text{FEV}_1$  has usually fallen to 1–1.5 L in an average man. Patients with COPD may adapt their breathing pattern and their behaviour to minimize the sensation of breathlessness. However, it is noticeable that the perception of breathlessness, as assessed using the 10-point Borg scale, varies greatly for individuals with the same degree of ventilatory capacity [502]. Mood is an important determinant of the perception of breathlessness in patients with COPD [502]. However, when the  $\text{FEV}_1$  has fallen to 30% or less of the predicted values (equivalent in an average man to an  $\text{FEV}_1$  of around 1 L), breathlessness

is usually present on minimal exertion [503]. Severe breathlessness is often affected by changes in temperature and occupational exposure to dust and fumes. Position has a variable effect on breathlessness. Some patients have severe orthopnoea that is relieved by leaning forward, whereas others find greatest ease when lying flat [504]. Breathlessness can be assessed on the MRC scale [505], which has been used extensively in epidemiological studies. The Borg scale and visual analogue scales have also been used to monitor the progress of specific symptoms and other questionnaires, such as the baseline dyspnoea index and the transitional dyspnoea index, have also been used [506].

A productive cough occurs in up to 50% of cigarette smokers [507]. In most patients with COPD, cough precedes the onset of breathlessness or appears with it and many patients may dismiss this symptom as a 'smoker's cough'. The MRC symptom questionnaire uses cough as a defining symptom of chronic bronchitis, i.e. a cough productive of sputum on most days for three consecutive months over two consecutive years [505]. Previous studies have shown no association between the presence of cough and sputum production and mortality [28] (see Fig. 23.3). However, a more recent study did indicate an association between cough and the development of airflow limitation [29].

Cessation of cigarette smoking produces resolution of the cough in 94% of smokers [159]; however, the airflow limitation often persists. The frequency of nocturnal cough does not appear to be increased in stable COPD [508]. In the presence of severe airway obstruction, with the generation of high intrathoracic pressures, paroxysms of cough may produce syncope [509] and cough fractures of the ribs [510].

Wheeze is common but not specific to COPD, since it is

due to turbulent airflow in large airways from any cause. The presence of wheeze was a pointer to a positive bronchodilator response in one study [511], although these data require confirmation.

Chest pain is common in patients with COPD but is often unrelated to the disease itself, and may be due to underlying ischaemic heart disease or gastro-oesophageal reflux [512]. Patients with COPD often complain of chest tightness during exacerbations of breathlessness, particularly during exercise, and this is sometimes difficult to distinguish from ischaemic cardiac pain. Pleuritic chest pain may suggest an intercurrent pneumothorax, pneumonia or pulmonary infarction.

Haemoptysis in association with purulent sputum may be due to inflammation or infection. However, this symptom should be treated seriously and the need for investigations for bronchial carcinoma should be considered.

Weight loss and anorexia are features of severe COPD and are thought to result from both a decrease in calorie intake and hypermetabolism [513].

Psychiatric morbidity, particularly depression, is common in patients with severe COPD, reflecting the social isolation and the chronicity of the disease [514]. Sleep quality is impaired in advanced COPD [515], which may contribute to the impaired neuropsychiatric performance.

### Occupation/smoking history

It is important to obtain a detailed smoking history in patients with COPD since the disease is rare in lifelong non-smokers. Although in general there is a negative relationship between the number of cigarettes smoked and the level of FEV<sub>1</sub>, there are huge individual variations that reflect differences in susceptibility to cigarette smoke [30,40]. In general symptomatic COPD develops after 20 pack-years of smoking.

Occupational exposure to dusts has an additive effect on the decline in lung function, as has been shown in coal-miners, where both smoking and years of dust exposure contribute to the decline in FEV<sub>1</sub>, although the contribution of smoking was three times as great as that of the average dust exposure in one particular study [85].

### Physical signs

The physical signs in patients with COPD are not specific to the disease and depend on the degree of airflow limitation and pulmonary overinflation. However, the sensitivity of physical signs for detecting or excluding moderately severe COPD is poor [516]. Variable degrees of tachypnoea may be present in patients with severe COPD and this is dependent on the type of clinical presentation of the disease (see below). Prolonged forced expiratory time (>5

s) can be a useful indicator of airway obstruction. Tar-stained fingers emphasize the smoking habit. In advanced disease cyanosis may be present, indicating hypoxaemia, but may be influenced by the background lighting or accentuated by polycythaemia, and therefore this sign is fairly subjective. The flapping tremor associated with hypercapnia is neither sensitive nor specific, and the often-reported papilloedema associated with severe hypercapnia is rarely seen.

Weight loss may also be apparent in advanced disease, as well as a reduction in muscle mass. Finger clubbing is not a manifestation of the disease and should suggest the possibility of complicating bronchial neoplasm or bronchiectasis. The breathing pattern is often characteristic, with a prolonged expiratory phase, some patients adopting pursed-lip breathing on expiration, which may reduce expiratory airway collapse [517] and may even improve oxygenation [518].

The use of the accessory muscles of respiration, particularly the sternomastoids, is often seen in advanced disease and these patients may adopt the position of leaning forward, supporting themselves with their arms to fix the shoulder girdle and allowing the use of the pectorals and latissimus dorsi to increase chest wall movement [519].

In the later stages of COPD the chest is often barrel-shaped, with kyphosis and an apparent increased antero-posterior diameter, horizontal ribs, prominence of the sternal angle and a wide subcostal angle. These are all signs of overinflation rather than anatomical changes. As a result of the elevation of the sternum, the distance between the suprasternal notch and the cricoid cartilage (normally three finger breadths) may be reduced, and an inspiratory tracheal tug may be detected, which has been attributed to the contraction of the low flat diaphragm [520]. The horizontal position of the diaphragm also acts to pull in the lower ribs during inspiration (Hoover's sign) [521]. Widening of the xiphisternal angle and abdominal protuberance occur, the latter due to forward displacement of the abdominal contents, giving the appearance of apparent weight gain. Increased intrathoracic pressure swings may result in indrawing of the suprasternal and supraclavicular fossae and of the intercostal muscles. A rise in jugular venous pressure may be seen on expiration.

On percussion of the chest there is decreased hepatic and cardiac dullness, indicating overinflation. A useful sign of gross overinflation is the absence of a dull percussion note, normally due to the underlying heart, over the lower end of the sternum.

Breath sounds may have a prolonged expiratory phase or may be uniformly diminished, particularly in the advanced stages of the disease. However, in a comparison of recorded breath sounds at comparable airflows, no difference was found between the intensity of the breath sounds in patients with COPD and normal subjects [522].

Wheeze, heard by the unaided ear or at the patient's mouth, is common in COPD [523]. Wheeze may be variably present on both inspiration and expiration but is not an invariable clinical sign [524]. Crackles may be present particularly at the lung bases, but are usually scanty, vary with coughing and cannot be distinguished from the persistent coarse crackles of bronchiectasis or the fine respiratory crackles of fibrosis or left ventricular failure [525].

### Cardiovascular examination

The presence of emphysema or overinflation of the chest produces difficulty in localizing the apex beat and reduces the cardiac dullness. The characteristic signs indicating the presence or consequences of pulmonary arterial hypertension may be detected in advanced cases. The heave of right ventricular hypertrophy may be palpable at the lower left sternal edge or in the subcostal angle. Heart sounds are generally soft, although the second heart sound may be exaggerated in the second left intercostal space. There may be a right ventricular gallop rhythm, with a third sound audible in the fourth intercostal space to the left of the sternum or in the epigastrium. The jugular venous pressure can be difficult to estimate in patients with COPD as it varies widely with respiration and is difficult to discern because of the prominent accessory muscle activity. When the fluid retention of cor pulmonale occurs there may be evidence of functional tricuspid incompetence, producing a pansystolic murmur at the left sternal edge. The liver may be tender and pulsatile, and a prominent *v* wave may be visible in the jugular venous pulse. The liver may also be palpable below the right costal margin as a result of the low diaphragm, due to the overinflation of the lungs.

Peripheral vasodilatation accompanies hypercapnia, producing warm peripheries with a high-volume pulse. Pitting peripheral oedema may also be present as a result of fluid retention. However, other causes of oedema, such as deep venous thrombosis, venous stasis and low serum albumin, should be considered.

### Types of clinical presentation

Many smokers are content to accept the development of cough with sputum production and exertional dyspnoea as an inevitable consequence of the smoking habit, and therefore often present to their doctor when the disease is at a fairly advanced stage. Relatively few patients are detected early in the disease process as a result of screening by spirometry. The BTS guidelines [4] encourage the use of spirometry in cigarette smokers in order to identify susceptible smokers with established airflow limitation. Repeated measurements over the course of several years will identify smokers with a rapid decline in FEV<sub>1</sub> who

could be targeted for smoking cessation and early intervention with treatment. Not all patients fulfil the criteria for the MRC definition of chronic bronchitis; breathlessness is the most common presenting symptom in patients with COPD. A description of symptoms that vary throughout the day and which are particularly worse in the morning is not a good discriminatory sign for those patients who show a response to bronchodilator or steroid therapy [526]. Some patients present initially to hospital during an exacerbation of the disease and claim that they have had no significant symptoms until that time. However, close questioning usually reveals the presence of progressive symptoms in most.

Two clinical patterns of the disease have been described, the so-called 'pink puffers' and 'blue bloaters'. The pink and puffing patient is thin, breathless and preserves blood gas values until late in the course of the disease and therefore does not develop pulmonary hypertension until the disease is very advanced. In contrast, the blue and bloated patient develops hypoxaemia and hypercapnia earlier and thus the complications of oedema and secondary polycythaemia. These represent the extreme ends of a spectrum, with most patients lying between these extremes. Although the presentation of these two extreme clinical patterns seems to be diminishing, it is important to recognize them since 'blue bloaters' have almost double the mortality rate of 'pink puffers' with similar degrees of airflow obstruction [419].

### Physiological assessment

The most important disturbance of respiratory function in COPD is obstruction to forced expiratory airflow. The degree of airflow obstruction cannot be predicted from the symptoms and signs [527] and therefore its assessment should be encouraged both in primary and secondary care. At an early stage of the disease conventional spirometry may reveal no abnormality. This results from the fact that the earliest changes in COPD affect the alveolar walls and small airways, so that a modest increase in peripheral airways resistance is not reflected in these conventional spirometric measurements [528]. Tests of small airway function, such as the frequency dependence of compliance, closing volume, flow-volume loops breathing air and helium/oxygen mixtures and flow rates at low lung volume, may be abnormal [355,529,530]. However, these tests are difficult to perform and have high coefficients of variation. Although they can distinguish smokers from non-smokers, they are only valid when elastic recoil is normal and there is no increase in large airways resistance, conditions seldom met even in mild COPD. They are therefore not recommended in normal clinical practice. By the time most patients present clinically, conventional spirometry is abnormal and the most useful and commonly employed test is the FEV<sub>1</sub>.

Spirometry

Spirometry is the most robust test of airflow limitation in patients with COPD. A low FEV<sub>1</sub> with an FEV<sub>1</sub>/forced vital capacity (FVC) ratio below the normal range is a diagnostic criterion for COPD [2–4]. The rate of decline of FEV<sub>1</sub> can be used to assess susceptibility in cigarette smokers, progression of the disease and reversibility of the airways obstruction. It is important that a volume plateau is reached when performing the FVC; this can take 15 s or more in patients with severe airways obstruction. If this manoeuvre is not carried out, the FVC can be underestimated. Since the FEV<sub>1</sub> is effort dependent, the traces must be checked to ensure maximum effort has been achieved [531] and in addition that full expiration has been performed [532]. It has been suggested that the standard ATS criteria [533] should be modified to encourage a maximum expiratory effort during the first part of the manoeuvre and then a ‘relaxed’ expiration when expiratory airflow falls to less than 200 mL/s [532]. The BTS guidelines [4] have equated the FEV<sub>1</sub> to disability and hence can be used as a guide to therapy (Table 23.6).

Flow–volume loops

Expiratory flows at 75% or 50% of VC have been used as a measure of airflow limitation and provide complementary information to the usual volume–time plot. There are problems with the reproducibility of these measurements, so that abnormal values must fall to below 50% of the predicted values. Flows at lung volumes less than 50% of VC were previously considered to be an indicator of small airways function but probably provide no more clinically useful information than measurements of FEV<sub>1</sub> [533]. Measurements of flow at fixed lung volumes are very variable in patients with COPD since volume calculated from flow at the mouth does not take account of thoracic gas compression during expiration. The flow–volume loop in

severe COPD shows a relatively preserved PEF followed by a rapid decrease in flow after the first 200–300 mL as airways collapse (see Fig. 23.11).

Peak expiratory flow

PEF can either be read directly from the flow–volume loop or measured with a hand-held peak flow meter. The hand-held instruments are relatively easy to use and are particularly useful for repeated measurements in asthmatics, since serial measurements during exacerbations or at home can reveal variations in response to therapy or spontaneous diurnal variability [534]. However, in COPD there is little daily change in PEF and many variations are often within the error of the measurement [535]. Although repeated measurements of PEF can be used in place of FEV<sub>1</sub>, single measurements are not useful as the variation is so high [536]. There are several theoretical reasons why FEV<sub>1</sub> is a better test than PEF in the diagnosis and assessment of COPD (Table 23.7), so that PEF is an inferior measurement of airways obstruction in COPD.

Lung volumes

Measurements of static lung volumes, such as TLC, RV and FRC, are used in patients with COPD to assess the degree of overinflation and gas trapping that results from loss of elastic recoil and collapse of the airways. Dynamic overinflation is recognized to occur particularly during exercise and may be an important determinant of symptoms such as breathlessness [349].

The standard method to measure static lung volumes using the helium dilution technique during rebreathing may underestimate lung volumes in COPD, particularly in those patients with bullous disease, where the inspired helium does not have time to equilibrate properly in the airspaces. The body plethysmograph uses Boyle’s law to calculate lung volumes from measurements of changes in

Table 23.6 BTS scheme for assessing patients with COPD.

	Clinical state	Results of measurements	Use of healthcare resources
Mild	Smoker’s cough, but little or no breathlessness. No abnormal signs	FEV <sub>1</sub> 60–79% of predicted. FEV <sub>1</sub> /VC and other indices of expiratory flow mildly reduced	Unknown: presymptomatic within the community
Moderate	Breathlessness (± wheeze) on exertion, cough (± sputum) and some abnormal signs	FEV <sub>1</sub> 40–59% of predicted often with increased FRC and reduced DLco. Some patients are hypoxaemic but not hypercapnic	Known to GP with intermittent complaints
Severe	Breathlessness on any exertion. Wheeze, cough prominent. Clinical overinflation usual, plus cyanosis, peripheral oedema and polycythaemia in some patients	FEV <sub>1</sub> <40% of predicted with marked overinflation. DLco variable, but often low. Hypoxaemia usual and hypercapnia in some patients	Likely to be known to hospital and by GP, with frequent problems and hospital admissions

FEV<sub>1</sub>, forced expiratory volume in 1 s; FRC, functional residual capacity; VC, vital capacity; DLco, diffusing capacity for carbon monoxide.

**Table 23.7** The reasons why FEV<sub>1</sub> is recommended as the measurement of choice in COPD.

---

The FEV <sub>1</sub> is a reproducible and objective measurement. There are well-defined normal ranges that allow for the effects of age, race and sex
It is relatively simple and quick to measure and can be measured at all stages of disease
The forced expiratory manoeuvre records not only FEV <sub>1</sub> but also FVC. An FEV <sub>1</sub> /FVC ratio less than 70% is diagnostic of airways obstruction. If the ratio is normal (>70%) and the test was performed well, the pattern is not obstructive and the diagnosis is not COPD.
PEF measurements cannot determine whether values are low because of obstruction or restriction
The variance of repeated measurements in the same person is well documented and is low
Studies of mortality and disability have shown that the FEV <sub>1</sub> predicts future mortality
Serial measurements provide evidence of disease progression
In COPD the relationship between PEF and FEV <sub>1</sub> is poor
PEF may underestimate the degree of airways obstruction in COPD

---

FEV<sub>1</sub>, forced expiratory volume in 1 s; FVC, forced vital capacity; PEF, peak expiratory flow.

mouth and box pressures during gentle panting against a closed shutter. This technique measures trapped air within the thorax, thus including poorly ventilated areas and therefore giving higher readings than the helium dilution technique. Estimation of FRC by whole-body plethysmography may reveal values as much as 1–2 L greater than those found with the helium dilution technique in patients with COPD [537]. However, delayed equilibration of pressure between the alveoli and mouth can result in an error that leads to overestimation of lung volumes [538].

X-ray planimetry has also been used in COPD to measure lung volumes [539] and this method can now be computerized. However, the accuracy of this measurement in COPD has been questioned [540].

### Reversibility to bronchodilators

The American, European and British Thoracic Societies (ATS, ERS and BTS) recognize that assessment of reversibility to bronchodilators is an essential part of the investigation and management of patients with COPD [2–4]. Reversibility tests are important in COPD for several reasons: (i) to help distinguish those patients with marked reversibility who have underlying asthma; (ii) to aid with future management; and (iii) because the FEV<sub>1</sub> after bronchodilator is the best predictor of survival. However, there is no agreement on a standardized method of assessing reversibility [541]. Reversibility is usually assessed by measuring changes in FEV<sub>1</sub> or PEF but could also be determined as a change in static lung volumes after bronchodilators, which may explain why some patients have improvement in symptoms with little spirometric change following a bronchodilator [542].

The use of bronchodilator testing in patients with COPD is limited by the variability of the FEV<sub>1</sub> measurement itself, which is reported to be less than 5% in normal subjects [543]. However, Tweeddale and colleagues [543] in a study of repeated measurements of FEV<sub>1</sub> on the same day found an SD of 102 mL that was independent of base-

line FEV<sub>1</sub>. Thus if the change in FEV<sub>1</sub> exceeds 170 mL it can be considered not to have arisen by chance. The ERS and BTS guidelines both recommend that changes should only be considered significant if they exceed 200 mL, which is supported by a recent study [544]. In addition to this absolute change in FEV<sub>1</sub>, a percentage change of 12% over baseline as a percentage of the predicted normal value has been suggested as a significant bronchodilator response by the ATS [2]; an improvement of 15% over baseline FEV<sub>1</sub> and a 200-mL absolute change has been suggested by ERS and BTS guidelines [3,4,545]. A third approach that has received less support is to express the change in FEV<sub>1</sub> as a percentage of the potential possible change, which is the predicted value minus the baseline value [535].

It is important when comparing studies of reversibility that the methodology of assessing bronchodilator response is similar. Unfortunately daily variations in airway smooth muscle tone may affect the response to bronchodilators in patients with COPD. Thus when airway smooth muscle tone is higher, and thus FEV<sub>1</sub> is lower, a response to bronchodilators may be more likely than when muscle tone is lower and FEV<sub>1</sub> is higher. In addition, airway calibre may alter drug deposition, adding further to the variability in the response [546]. Thus as many as one-third of those patients initially shown to have a response to a bronchodilator may on retesting on a different day have no response [511]. For this reason it has been suggested that measurement of the FEV<sub>1</sub> after bronchodilator is a better estimate of progression of airway obstruction.

It is usually recommended that the response to a bronchodilator be assessed with a large dose, either using repeated doses from a metered-dose inhaler or via the nebulized route, since this produces a larger number of patients with a significant response than if a small dose is given by metered-dose inhaler [547]. In some cases the addition of a second drug, such as an anticholinergic, to a  $\beta$ -agonist produces a further increase in FEV<sub>1</sub> [548]. Thus it is worth while assessing the bronchodilator response to both  $\beta$ -agonist and anticholinergic drugs in patients with COPD.

### Reversibility to corticosteroids

Whether all patients with symptomatic COPD should have a formal assessment of steroid reversibility remains controversial [2,4]. However, this is the recommendation of the BTS guidelines [4]. The most common regimen is the administration of 30 mg of prednisolone for a period of 2 weeks. Those patients who have previously shown a response to nebulized bronchodilators are more likely to show a response to steroids [526]. However, it is not possible to predict the response to corticosteroids in any individual patient and therefore to avoid the need for a trial of steroids in all patients. There is also no relationship between the response to oral steroids and  $DLCO$ , as a surrogate measurement of emphysema, or atopic status [549].

An alternative approach is to assess the response to inhaled steroids. Weir and coworkers [550,551] suggested a 6-week trial of inhaled steroids, measuring the  $FEV_1$  before and after and/or the average PEF of the first 5 days and the last 5 days. Whether a trial of oral or inhaled steroids is the best way to assess steroid reversibility is still a matter of debate; however, one small placebo-controlled study showed improvement following inhaled beclomethasone (beclomethasone) that was not increased by subsequent oral prednisolone [552].

However, an acute response in the  $FEV_1$  in a bronchodilator reversibility test does not necessarily predict a symptomatic response [553]. For example the improved exercise tolerance in patients with COPD in response to ipratropium bromide was not dependent on whether the patient had previously shown a significant bronchodilator response to this drug [554]. Similarly, improvements in exercise tolerance have been shown with  $\beta_2$  agonists [555] and corticosteroids [556] in patients who show no significant  $FEV_1$  response.

### Gas transfer for carbon monoxide

$DLCO$  values are below normal in many patients with COPD and although there is a relationship between  $DLCO$  and the presence of microscopic emphysema [207,208], the severity of the emphysema in an individual patient cannot be predicted from the  $DLCO$ . Neither is a low  $DLCO$  specific for emphysema. Thus a low  $DLCO$  is suggestive of a significant degree of alveolar destruction, probably as a result of emphysema, although a normal  $DLCO$  does not exclude a diagnosis of COPD. The methodology to assess  $DLCO$  may also influence the result in patients with COPD. The method of Ogilvie and colleagues [557] measures the rate of carbon monoxide uptake during a 10-s breath-hold and relates this to the alveolar volume, derived by adding the inspired volume to the RV measured in a separate helium dilution test. A now more widely used method is the single-breath technique [558], which uses alveolar volume calculated from helium dilution during the single-breath

test. This underestimates alveolar volume in patients with severe COPD, producing a lower value for  $DLCO$ .

### Arterial blood gases

Measurement of arterial blood gases is essential in patients with COPD to confirm the degree of hypoxaemia and hypercapnia and, in acute exacerbations particularly, to determine the hydrogen ion concentration. It is recommended in patients with an  $FEV_1$  <40% of their predicted value [4]. It is essential to record the inspired oxygen concentration when reporting blood gases, and it is also important to note that it may take at least 30 min for a change in inspired oxygen concentration to have its full effect on the  $PaO_2$  because of long time constants for alveolar gas equilibration in COPD.

Pulse oximetry and transcutaneous oxygen tension measurements are increasingly used in intensive care units. They can be useful in measuring changes in oxygenation during an acute exacerbation of COPD. However, they should not replace an assessment of blood gas tensions, since measurements of  $Paco_2$  are often required.

Acid–base status can also be assessed from the arterial pH (hydrogen ion concentration) and bicarbonate concentration. From the modified Henderson–Hasselbalch equation,  $[H^+] = k \times Paco_2 / [HCO_3^-]$ , where  $[H^+]$  is the hydrogen ion concentration,  $k$  a constant and  $[HCO_3^-]$  the bicarbonate concentration, increases in  $Paco_2$ , which can occur rapidly, can be compensated by renal conservation of bicarbonate, a relatively slow process. Acid–base status, particularly mixed respiratory and metabolic disturbances, can be characterized by plotting values on an acid–base diagram [559]. Such a diagram is useful in apportioning the relative contributions of primary respiratory and metabolic causes of the acid–base disturbance and, when serial values are plotted, the response to treatment.

### Exercise tests

Exercise produces an increase in oxygen consumption and carbon dioxide production from skeletal muscle. Patients with COPD have the same oxygen consumption for a given workload as normal subjects; however, their dead space ventilation is higher and so a larger minute ventilation is needed to maintain carbon dioxide constant. Since in many patients expiratory airflow is limited within the tidal volume range, the only way to increase minute ventilation is to increase inspiratory flow and/or shift the end-expiratory position [560]. Both of these manoeuvres are problematic in patients with COPD, requiring more work from already compromised inspiratory muscles or resulting in progressive overinflation, which increases both the work of breathing and symptoms. There is still debate about whether under these circumstances exercise is

limited by the development of inspiratory muscle fatigue [561].

The cardiovascular responses to exercise are, in general, considered to be appropriate [562], although the increase in stroke volume is less than normal in severe COPD, perhaps due to a combination of overinflation and pulmonary hypertension. However, metabolic acidosis develops at lower work rates in patients with severe COPD [563]. In a study of 97 patients with COPD during progressive cycle exercise, exercise was limited by dyspnoea in 40% and by leg fatigue in 25% [564], probably reflecting the general debility present in patients with COPD [565].

Three forms of exercise test can be performed that provide useful information.

#### **Progressive symptom-limited exercise**

In this test the patient is encouraged to maintain exercise, on a treadmill or a cycle, until symptoms prevent them from continuing. The usual criteria for defining a maximum test are a heart rate of greater than 85% of predicted or a ventilation greater than 90% predicted. The reproducibility of the test from day to day is good [566] and the results are useful, particularly when simultaneous ECG and blood pressure monitoring are performed in order to assess whether coexisting cardiac or psychological factors contribute to exercise limitation.

#### **Self-paced exercise**

These tests are easy to perform and give information on more sustained exercise, which may be more relevant to performance in everyday life. The 6-min walk is the most commonly used test [567] and has a similar reproducibility to the previously described 12-min walk [568], with a coefficient of variation of around 8%. Shortening the walk to 2 min reduces the reproducibility [569]. It has been suggested that a learning effect may affect the result of repeated tests, although this view is debated [569]. In addition the test is only useful in patients with moderately severe COPD ( $FEV_1 < 1.5L$ ) who would be expected to have an exercise tolerance of less than 600 m in 6 min. There is only a weak relationship between walking distance and  $FEV_1$  [570].

#### **Steady-state exercise**

In this test patients exercise at a sustainable percentage of maximum capacity for 3–6 min and blood gases are measured, enabling calculation of the dead space–tidal volume ratio and shunt. This assessment is seldom required in patients with COPD.

Other more complex tests, such as assessment of the lung pressure–volume curve, are difficult to undertake, requiring measurement of oesophageal pressure with a

balloon, and are not part of the routine assessment but may be necessary in special circumstances.

#### **Sleep studies**

Patients with COPD become more hypoxaemic during sleep, particularly REM sleep [571]. There is no evidence that measurement of nocturnal hypoxaemia provides any further prognostic or clinically useful information in the assessment of patients with COPD unless coexisting sleep apnoea syndrome is suspected [572].

#### **Non-physiological assessments**

In patients with severe COPD, identifying polycythaemia is important since it predisposes to vascular events, and there is some evidence that venesection may improve exercise tolerance [573,574]. Polycythaemia should be suspected when the haematocrit is greater than 47% in women and more than 52% in men and/or the haemoglobin is greater than 16 g/dL in women and more than 18 g/dL in men, provided other causes of spurious polycythaemia, such as decreased plasma volume due to dehydration, can be excluded.

There is no indication for measuring blood biochemistry routinely in patients with clinically stable COPD [4]. The levels and phenotype of  $\alpha_1$ -AT should be measured in all patients under the age of 40 years and in those with a family history of emphysema at an early age.

Routine ECG is not required in the assessment of patients with COPD [4], and is an insensitive technique in the diagnosis of cor pulmonale.

#### **Radiology**

There are no features on a plain posteroanterior chest radiograph specific for COPD. The features that are usually described are those of severe emphysema. However, there may be no abnormalities, even in patients with very appreciable disability [575]. Recently improvements in imaging techniques, particularly the advent of high-resolution CT (HRCT), have provided a more sensitive means of diagnosing macroscopic emphysema in life [576–578].

#### **Plain chest radiography**

On both plain chest radiography [579] and CT [580] the trachea may be seen rarely to be narrowed in its coronal section, the so-called ‘sabre-sheath’ trachea, in patients with COPD. This unusual association occurs in patients over the age of 50. Its pathogenesis is unclear but may be related to abnormal thoracic pressure gradients generated in these patients; it is unlikely to contribute significantly to the airflow obstruction.

Bronchial wall thickening, shown as parallel line opacities on plain chest radiography, has been described in clinico-radiological series of patients with COPD [581], although this is not a universal finding in all studies [582]. Bronchial wall thickening has also been observed on HRCT in smokers and ex-smokers, many of whom had chronic bronchitis [583]. However, many of these findings may relate to coincidental bronchiectasis.

The most reliable radiographic signs of emphysema can be divided into those due to hyperinflation, those due to vascular changes and those due to bullae. Overinflation of the lungs results in the following.

1 Low flattened diaphragms (Fig. 23.15). Abnormally low diaphragms are present when the border of the diaphragm in the mid-clavicular line is at or below the anterior end of the sixth [584] or seventh [585] rib. Flattened diaphragms are present when the maximum perpendicular height from a line drawn between the costal and cardiophrenic angles to the border of the diaphragm is less than 1.5 cm.

2 Increase in the retrosternal airspace (Fig. 23.15b), which can be demonstrated on the lateral film at a point 3 cm below the manubrium, occurs when the horizontal distance from the posterior surface of the aorta to the sternum exceeds 4.5 cm [575].

3 An obtuse costophrenic angle on the posteroanterior or lateral chest radiograph.

**Fig. 23.15** Plain chest radiographs of generalized emphysema particularly affecting the lower zones. (a) PA radiograph showing low, flat diaphragms (below anterior ends of seventh ribs); obtuse costophrenic angles; reduced vessel markings in lower zones which are transradiant. (b) Lateral radiograph; low, flat and inverted diaphragm and widened retrosternal transradiancy (white arrows) which approaches the diaphragm inferiorly (black arrows).

4 The inferior margin of the retrosternal airspace is 3 cm or less from the anterior aspect of the diaphragm (Fig. 23.15b).

The vascular changes associated with emphysema result from loss of alveolar walls and are shown on the plain chest radiograph by the following.

1 A reduction in size and number of pulmonary vessels, particularly at the periphery of the lung.

2 Vessel distortion, producing increased branching angles, excess straightening or bowing of vessels.

3 Areas of transradiancy.

On fluoroscopy the range of diaphragmatic movement, normally 6–8 cm and always greater than 3 cm, is often only 1 cm in severe COPD. Occasionally the flattened diaphragms may be drawn upwards in parallel in inspiration, a motion different from true paradoxical movement due to paralysis of the phrenic nerve. In the latter, inspiratory sniffing gives rise to a sharp upward movement of the convex diaphragm, quite different from the slight upward movement of a flattened diaphragm in COPD.

Assessment of the vascular loss in emphysema clearly depends on the quality of the X-ray film. A general increased transradiancy may be due to an overexposed chest film. Focal areas of transradiancy surrounded by hair-line walls represent bullae [586]. These may be multiple, as part of a generalized emphysematous process, or localized. An 'increase in lung markings' rather than areas of increased transradiancy has often been described in patients with COPD. The cause of these changes is unknown but may be at least contributed to by non-vascular linear opacities due to scarring.

In early studies it was considered that the radiographic changes of emphysema on a plain chest film did not correlate well with pathological findings of emphysema. However, the method of defining emphysema pathologi-

cally had not been standardized in many of these studies; in those where standardization had been employed, this was usually based on a semi-quantitative picture-grading technique to assess macroscopic emphysema [575,587–589]. The accuracy of diagnosing emphysema on the plain chest film increases with the severity of the disease and has been reported as being 50–80% accurate in patients with moderate to severe disease [590]. However, the sensitivity has been reported as being as low as 24% in patients with mild to moderate disease [588].

A recent study has revived interest in the diagnosis of emphysema by plain chest radiography and suggests that the careful application of standardized radiographic criteria produces results as accurate in the diagnosis of macroscopic emphysema as CT [591]. However, many of the criteria remain subjective.

### Computed tomography

CT has been used since the early 1980s to detect and quantify emphysema [592]. Studies using CT can be divided into those using visual assessment of low-density areas of the scan, which can be either semi-quantitative or quantitative, and those using CT lung density to quantify areas of low X-ray attenuation. These studies divide roughly into those measuring macroscopic and microscopic emphysema respectively.

A visual assessment of emphysema on CT (Fig. 23.16) reveals:

- 1 areas of low attenuation without obvious margins or walls;
- 2 attenuation and pruning of the vascular tree;
- 3 abnormal vascular configurations.

The sign that correlates best with areas of macroscopic emphysema is an area of low attenuation [593,594]. Several studies have shown that visual interrogation of the scan can locate areas of macroscopic emphysema subsequently assessed in postmortem or resected lungs [207,594–597]. The problem with these correlations is that the emphysema is often assessed by a picture-grading score, which does not measure emphysema on a linear scale [230,595,596].

However, visual assessment of the extent of macroscopic emphysema by CT is insensitive, subjective and has a high intraobserver and interobserver variability [593,598,599]. Thus in most of these studies CT tended to underestimate the severity of the disease; in particular centrilobular lesions smaller than 5 mm were missed [598]. Interestingly the use of high-resolution, thin-cut (1–5 mm) sections does not improve the detection of mild emphysema, for although it shows the parenchymal destruction well it is less good at showing the vascular changes [599].

It is possible using HRCT to distinguish the various types of emphysema, particularly when the changes are not severe [593,599,600]. The distinction between the types of emphysema depends on the distribution of the lesions,

(a)

(b)

**Fig. 23.16** CT HLTCT emphysema, showing diffuse panlobular emphysema (a), and more patchy centrilobular emphysema with bullae (b).

those of centrilobular emphysema being patchy and prominent in the upper zones, whereas those of panlobular emphysema are diffuse throughout the lung zones [599]. However, more recent pathological studies suggest that both the major types of emphysema can occur in the same patient [199,201].

A more quantitative approach for assessing macroscopic emphysema has been taken by Müller and colleagues [601] who described a more objective method of highlighting pixels within the lung fields in a predetermined low-density range, between –910 and –1000 Hounsfield units, the so-called ‘density mask’ technique. The choice of the density range is fairly arbitrary, although these workers were able to show a good correlation

between pathological emphysema scores and CT 'density mask' score. However, they indicated that this technique may miss areas of mild emphysema. In addition no study has validated the comparison of horizontal slices obtained by CT or by section of fixed lung slices and the parasagittal lung slices used by Thurlbeck and coworkers [230] to obtain pathological scores for macroscopic emphysema.

A more quantitative way of measuring emphysema, particularly at the microscopic level, uses measurements of CT lung density. CT density is expressed as a linear scale in Hounsfield units (water = 0, air = -1000). In this range, CT lung density is a direct measure of physical density and is determined by the relative mix of air, blood and interstitial fluid in tissue. Thus as emphysema develops a decrease in alveolar surface area would occur as alveolar walls are lost, associated with an increase in distal airspace size, which would decrease lung CT density in association with a decrease in lung function. Several studies have assessed CT lung density in normal subjects [602,603]. However, the range of normality has yet to be standardized particularly with respect to lung volume, which changes CT lung density [604,605]. If CT is to be used to measure microscopic emphysema, then care should be taken to standardize the scanning conditions, particularly the lung volume [606], and to calibrate the CT scanner, since these factors affect CT lung density [603].

Frequency distributions of the CT lung density values from the matrix of picture elements (pixels) from a CT lung slice can be generated and are shown to be skewed, with a tail of high-density values produced by large

vessels and airways. In emphysema there is an increase in the numbers of low-density pixels and the whole curve is shifted to the left [8] (Fig. 23.17). The lowest 5th percentile of the CT density histogram was used to characterize the CT lung density in 28 patients undergoing lung resection for peripheral lung tumours. Respiratory function and CT (two slices) were performed 48h before thoracotomy [207]. Emphysema was measured in the resected lung as AWUV (see p. 631). There was a significant correlation between CT lung density and AWUV. In addition AWUV correlated with Kco. Since these patients were surgical candidates they had relatively mild, largely microscopic emphysema. Indeed only five individuals had greater than 5% of the surface area of the mid-sagittal slice showing macroscopic emphysema. Moreover, the correlation between AWUV and CT lung density appeared to be independent of the presence of macroscopic emphysema. This relationship was also found in a larger group of normal subjects and patients with emphysema, the latter with a wide range of functional impairment. In these studies CT lung density correlated with  $DL_{CO}/\dot{V}_A$  [607] and with the shape parameter  $k$  of the lung pressure-volume curve [361].

More studies are required before CT lung density can be used as a standardized technique to quantify microscopic emphysema. It is particularly important to define the range of normality and to correlate the measurements with normal values of distal airspace size, as a defining characteristic of emphysema [209]. In addition, standardizing the calibration of CT scanners and the lung volume

**Fig. 23.17** CT density histogram of (a) a subject with no emphysema and (b) a patient with severe emphysema. The shaded area represents the lowest 5% of the distribution.

at which scans should be performed [605] is required for multicentre studies. However, based on present knowledge, CT is the most sensitive and specific imaging technique for assessing emphysema in life and can detect mild emphysema in symptomatic patients with a normal chest radiograph [608]. Preliminary studies also suggest that CT may be able to detect the progression of emphysema [609].

### **Pulmonary hypertension/cor pulmonale**

The development of right ventricular hypertrophy or enlargement produces non-specific cardiac enlargement on the plain chest radiograph. The development of pulmonary hypertension can be assessed from the plain chest radiograph; however, in most studies measurements have been made in diverse conditions, including mitral stenosis, and the results have been extrapolated to patients with cor pulmonale, which may not be entirely valid. The most widely used measurement to assess the presence of pulmonary hypertension is the width of the right descending pulmonary artery, measured just below the right hilum, where the borders of the artery are delineated against air in the lungs laterally and the right main stem bronchus medially. The upper limit of the normal range of the width of the artery in this area is taken as 16 mm in males and 15 mm in females [610]. Other studies have suggested an upper limit of normal ranging between 16 and 20 mm, which gives a sensitivity of detecting a pulmonary arterial pressure greater than 20 mmHg of 68–95%, with a specificity of 65–88% [611–613]. Although these measurements can be used to detect the presence or absence of pulmonary arterial hypertension, they cannot accurately predict the level of the pulmonary arterial pressure and therefore can only be used as a screening test.

### **Emphysematous bullae**

A bulla has been defined arbitrarily as an emphysematous space greater than 1 cm in diameter [189]. Bullae may give rise to spontaneous pneumothorax, remain undetected on a chest radiograph or indicate the presence of more widespread pulmonary emphysema.

Whether a bulla is detected on a chest radiograph depends on its size and the degree to which it is obscured by overlying lung. Some bullae may only be seen on the lateral film. On the plain chest radiograph, bullae appear as localized avascular areas of transradiancy, usually separated from the rest of the lung by a curvilinear hair-line wall. In the absence of such a radiological sign, it is extremely difficult to detect and quantify the number of bullae [587]. Marked compression of the lung may be seen and bullae may also depress the diaphragm. Diaphragmatic depression is sometimes localized, the upper surface of the diaphragm showing a slight convexity downwards; the fine line of the bulla wall may be

detectable at the lateral edges of the convexity. Bullae rarely displace the heart or trachea, although sometimes they extend across the retrosternal space to produce a fine convex line in the opposite lung. Fluoroscopy of large bullae may show deviation of the mediastinum to the opposite side on expiration due to air trapping.

CT (Fig. 23.16) is much more sensitive than plain chest radiography and can be used to determine the number, size and position of the bullae [614]. Ventilation of the bullae can also be assessed using inspiratory–expiratory images [614,615]. It is also possible to estimate the volume of bullae by measuring the area of the bullae in each CT lung slice [586]. Many techniques used in the past to assess a patient's suitability for bullectomy, such as bronchography and pulmonary angiography, have now been replaced by CT [586,615].

### **Clinical features and physiology**

Exertional dyspnoea is the usual presenting feature in patients with bullous disease, although a single bulla of moderate size is unlikely to produce symptoms when the remaining lung is normal. Occasionally a bulla presents as a chance finding on a chest radiograph. Bullae may also present as a pneumothorax and occasionally a bulla may be misinterpreted as a pneumothorax (see Fig. 44.9) in a breathless patient and a chest drain inserted directly into the bullous cavity. Bullae occasionally become infected, in which case there may be a fluid level with, sometimes, surrounding consolidation. Infection may result in closure of the bronchial connection, shrinkage or even obliteration of the bulla [616]. Occasionally in a patient with a large bulla, clinical examination may show asymmetrical overinflation of the chest and reduction of chest wall expansion, but this is not a reliable sign.

Respiratory function tests may be non-specific and may simply be those of COPD [586,617,618]. Almost always some degree of airway obstruction is present, which may result from concomitant diffuse emphysema or airways disease, or as a result of the loss of lung elastic recoil that accompanies large bullae [620]. Overinflation is almost always present but is underestimated if measured by the helium dilution technique rather than by plethysmography [619]. Gas exchange is usually impaired as shown by a reduced  $TLCO$ . The  $Kco$  may reflect the quality of the non-bullous lung if the bulla is non-ventilating and may be helpful in making a decision concerning surgery [620].

### **Treatment**

The only treatment considered for large bullae is surgical obliteration [192,621,622]. The selection of patients suitable for surgery is critical. Surgery should not be offered to patients who are asymptomatic, since the operation does have an appreciable risk. The principal indication for

surgery is progressive dyspnoea. The best surgical results are in younger patients with large bullae, minimal airways obstruction and normal surrounding lung [617]. In those with airflow limitation it has been difficult to determine which patients benefit from bullectomy. A critical feature is the quality of the non-bullous lung. Studies using CT have shown that the airflow limitation is determined by the degree of emphysema in the non-bullous lung rather than the extent of the bullous disease [620]. Patients with bullae occupying one lung less than 50% of an FEV<sub>1</sub> of less than 1 L or hypercapnia carry a high risk of a poor response to surgery.

Pulmonary angiography can be used to demonstrate preserved vasculature in surrounding collapsed lung, which if present would suggest that removal of the bullae would improve function. Quantitative perfusion scanning may also demonstrate retained perfusion in the collapsed peri-bullous lung, which may improve after operation [621]. However, other techniques, such as bronchspirometry and bronchoscopic inert gas techniques, have not improved the ability to predict a successful operation. Thus there appears to be no technique that predicts whether bullectomy results in expansion and improved function in the surrounding lung, which is the object of the operation.

Several techniques have been described to remove bullae including excision, plication, marsupialization and intracavity drainage. The aims of surgery are to obliterate the bullous space and restore the elastic integrity of the lung. Improvement in FEV<sub>1</sub> after removal of a bulla of 500 mL or less, particularly in a patient with associated diffuse emphysema, is unlikely to be an effective treatment considering the risks of the surgical intervention. Most operations are performed by a conventional lateral thoracotomy, although bilateral bullae can be approached through a median sternotomy [623]. Superficial bullae have also been dealt with using thoracoscopic and laser techniques [624]. An alternative approach has been the use of intracavity drainage. This technique was originally described by Monaldi, and is often restricted to patients who are a poor risk for general anaesthesia, since the technique can be performed under local anaesthesia [625].

The results of surgery for bullous disease have been published by several authors [617,623–629] but in relatively small numbers of patients. The perioperative mortality in published series ranges from 0 to 20% in patients with a wide range of disability, and hence operative risk. The best functional results occur in patients with mild symptoms and relatively well-preserved pulmonary function. Those with small bullae (<1 L), poor overall lung function and diffuse emphysema have least functional improvement and in these the functional improvement has to be weighed against the risk of surgery. Studies of long-term follow-up of patients after surgery indicate that once removed, giant bullae do not recur [621,623]. The initial improvement following

surgery appears to be maintained, and the subsequent decline in lung function depends on the condition of the remaining lung. As with those patients with generalized COPD, those who continue to smoke show a more rapid decline in FEV<sub>1</sub> [192]. Lung volume reduction surgery is discussed separately on p. 679.

## Prevention (see also Chapter 10)

Tobacco smoking is the major aetiological factor in COPD, outweighing all other factors. In most patients the disease is theoretically preventable and thus cessation of cigarette smoking is the single most important way of affecting the outcome. Other important aetiological factors, such as atmospheric pollution, are also preventable. Unfortunately, in most developing countries the trends for both these factors are upwards. In the UK around 31% of men and 29% of women are current cigarette smokers, and around 80–90% of patients with COPD have been regular smokers at some time in their lives [630]. At least 90% of smokers are aware of the adverse health effects of cigarette smoking, 70% wish to give up smoking, and the majority of these have made a serious attempt to quit [631]. However, only 40% of regular smokers have succeeded in quitting cigarette smoking by age 60 [632]. Nicotine in tobacco smoke is addictive and regular smokers who reduce or cease their nicotine intake experience the characteristic withdrawal syndrome resulting from nicotine craving, in the form of anxiety, lack of concentration, irritability, restlessness and increased appetite. Nicotine addiction develops relatively rapidly and withdrawal symptoms can be shown to occur even in adolescent smokers [633]. Thus a critical preventive measure is to reduce the initiation rate of children starting smoking in the UK, which currently runs at 450 children per day [634]. This could be achieved by providing information to reduce the attractiveness and the peer pressure that causes children to start smoking, and by legislating against cigarette advertising and the availability of cigarettes to children. There is no doubt that tobacco advertising does increase tobacco consumption and therefore legislation against tobacco advertising is the single most important factor in trying to reduce the number of young people taking up the smoking habit.

## Smoking cessation

Since smoking cessation reduces the subsequent decline in lung function, particularly in those with an accelerated decline in FEV<sub>1</sub> [35], smoking cessation is the single most important step that can be taken to prevent the progression of the disease. This is particularly true during the early stages of COPD, when both symptoms and lung function may improve, whereas in older men smoking cessation only reduces the rate of decline in FEV<sub>1</sub> [36,635].

Although in advanced disease quitting smoking may not improve pulmonary function, symptoms such as cough may still improve [36].

All patients who smoke should have the implications for their future health discussed. Even the briefest of advice from health professionals can lead to smoking cessation in those who wish to quit. Asking about smoking habit in every patient may also have a positive reinforcing effect against starting smoking in non-smokers. The reported success rates of smoking cessation come mainly from studies conducted in a primary care setting and vary between 10 and 30% [636]. These figures cannot necessarily be extrapolated to other circumstances, such as an outpatient clinic. A BTS study [637] conducted in the setting of a respiratory outpatient clinic indicated that even brief advice by a physician on smoking-related diseases could produce a long-term success rate of 5.1%, which increased to 8.1% when the doctor sent brief letters to the patients encouraging abstinence. A recent review of the literature suggests that in those who request extra help to stop smoking, when given in the form of nicotine replacement or even contact with a support group, the success rate can be up to 25% [636].

Although it would seem logical, as in other addictions, to suggest a reduction in nicotine levels by a gradual reduction in the number of cigarettes smoked so as to reduce the severity of withdrawal symptoms [638], it has been shown that patients who gradually cut down the number of cigarettes tend to inhale more in order to maintain their usual blood nicotine levels [639]. In one randomized study comparing gradual reduction with abrupt quitting on a target date, the latter was more successful [640]. It has also been shown that those who are unable to quit abruptly are not successful in reducing their consumption of cigarettes over the long term [641,642].

The intensity of the strategy employed in a cessation programme should depend on the motivation of the patient to give up smoking. There is no difference in the success rates between regimens involving brief interven-

tion and those with more prolonged intervention in unselected smokers, whereas it is clear that those who are motivated to attend smoking cessation clinics have a better chance of long-term cessation than those who have a brief intervention by the general practitioner. Thus patient motivation influences all smoking cessation trials [636]. It is therefore better to put time and effort only into those patients who are motivated to give up and only a brief intervention in those with less motivation.

If any additional resources are employed in smoking cessation, it is important that patients are given clear instructions with a clear strategy and that success rates are corroborated with breath carbon monoxide measurements [643], although this technique can be slightly inaccurate in patients with COPD [644]. Support groups to help smokers quit are successful in patients with motivation [645]. Pharmacological aids are also available but, again, are particularly successful in those who are motivated. Meta-analysis of randomized controlled trials of nicotine gum found a clear benefit in terms of abstinence rates at 1 year (23% vs. 13%) in a smoking cessation clinic but no effect in a general practice setting (11% vs. 12%) [646]. Similar abstinence rates at 1 year have been quoted in a general hospital study in the UK [647]. In general poor compliance has been reported for the use of nicotine gum, which many find unpleasant to use [647,648].

The development of nicotine skin patches allows a slow infusion of nicotine that creates plasma nicotine levels up to half those produced by smoking. Trials have been carried out with nicotine patches and indicate that similar success rates to nicotine chewing gum can be achieved [649] and that these, unlike nicotine chewing gum, may be achievable in settings other than smoking cessation clinics [650,651]. An advantage in terms of sustained cessation rates has even been demonstrated in the primary care setting [652].

Based on a review of the literature, a strategy for smoking cessation has been suggested by Foulds and Jarvis and is shown in Table 23.8.

**Table 23.8** Smoking prevention and cessation strategy for medical outpatients. (Modified from Foulds & Jarvis [636].)

Intervention	To whom?	Time per patient	Success rate*
Ask about smoking, record in notes	All attenders	10s	Prevention?
Measure carbon monoxide, give advice plus leaflet	Smokers (no extra help requested)	4 min	4%
Prescribe nicotine replacement, arrange quit-date plus follow-up	Smokers who ask for extra help	15 min	10%
Group treatment with nicotine replacement (5×1 h per group)	Smokers who ask for more support	22.5 min	25%
Overall strategy	All patients	mean 2.3 min per patient	5.8% of smokers

\* A 'success' is a patient who stops smoking immediately following the intervention and maintains abstinence for at least 1 year.

### Atmospheric pollution (see also Chapter 11)

Although the traditional atmospheric air pollutants that resulted from the burning of fossil fuels, such as black smoke and sulphur dioxide, have decreased considerably in developed countries, recent evidence has implicated other pollutants derived increasingly from vehicle traffic, such as ozone and fine particulate air pollution, in the exacerbations and increased mortality in patients with COPD [62,63]. These effects occur at relatively low levels and have prompted the UK Government recently to introduce new air pollution standards for these pollutants. A biologically plausible hypothesis has been proposed to account for the harmful effects of particulate air pollution at such low levels that implicates the reactivity of the particles as a result of their ultrafine size and their oxidative properties, which create airway inflammation [65]. As a result it seems justified, if practical, for patients with COPD to stay indoors and certainly to sleep with closed windows during episodes of high air pollution.

## Long-term management

### Bronchodilators

Bronchodilator therapy is the cornerstone of treatment to reduce symptoms and increase exercise tolerance in patients with COPD. In contrast to bronchial asthma, where bronchodilator therapy can return ventilatory capacity to normal in mild to moderate disease, the effects are small in patients with COPD because of structural changes within the airways. Indeed the change with a bronchodilator, which often falls within the normal variability of the measurement of FEV<sub>1</sub>, may still have clinical relevance. Thus symptomatic relief is not always accompanied by significant functional improvement. The principal symptomatic bronchodilators ( $\beta_2$  agonists, anticholinergic drugs and theophylline derivatives) have as their primary action relaxation of airway smooth muscle and hence decrease airways resistance [653]. However, in addition, these drugs may reduce the overinflation of the lungs characteristic of COPD, allowing the lungs to empty more completely [654]. The  $\beta_2$ -agonist drugs have been shown to increase ciliary beat frequency and so accelerate mucociliary clearance, which is impaired in COPD [655]. Although anticholinergic drugs may be considered theoretically to have an adverse effect on mucociliary clearance, clinical studies suggests that this is not the case. There is still considerable controversy regarding the proposed property of theophyllines in increasing respiratory muscle endurance and strength [656,657]. The proposed anti-inflammatory actions of both  $\beta_2$  agonists and theophyllines have recently received considerable attention, particularly in the case of theophyllines [658]. However, the major effect of these drugs is on changes in airway calibre secondary to airway

smooth muscle relaxation. It should be emphasized that relatively small changes in airway dimensions can have major effects on respiratory mechanics, which may be translated into improvement in symptoms and exercise capacity [659]. Thus inhaled bronchodilators may reduce symptoms even when there is little demonstrable reversibility in terms of FEV<sub>1</sub>.

### $\beta$ -Agonists

Inhaled  $\beta_2$  agonists (see Chapter 9) are preferred to oral preparations, since they are as efficacious as oral preparations in much smaller doses and have fewer side-effects [660]. Oral and intravenous  $\beta_2$  agonists have vasodilator properties [661,662] but these effects are unlikely to have any clinical significance in patients with COPD. The  $\beta_2$  agonists have a relatively rapid onset of action and therefore are used for symptomatic relief and can also increase exercise tolerance in patients with COPD [511,555,556,663,664].

The IPPB trial group examined a group of 65 patients with COPD. The response to 250  $\mu$ g of inhaled isoprenaline was tested repeatedly over 3 years [511]. The majority of these patients showed significant bronchodilatation to the  $\beta$  agonist at one or more visits during this trial. There appears to be a very small dose-response relationship to  $\beta_2$  agonists in terms of the change in FEV<sub>1</sub> in patients with COPD [526,556,663]. Patients with the largest response to  $\beta_2$  agonists are more likely to respond to corticosteroid therapy [526,665]. Even in those who show no significant improvement in FEV<sub>1</sub>, treatment with  $\beta_2$  agonists may improve exercise tolerance [556,664]. The view that older patients with COPD are less likely to respond to a  $\beta_2$  agonist [548], perhaps as result of loss of  $\beta$  receptors [666], is not universally accepted [544]. Neither is there any evidence that the response to a  $\beta$  agonist diminishes with time [663]. Patients with COPD should be told to take their  $\beta_2$  agonists as required, although those with severe disease may prefer to take regular doses three to four times daily to obtain symptomatic relief. The concerns that have been expressed over the safety of  $\beta_2$  agonists in patients with bronchial asthma [667] have also been applied to patients with COPD [668]. In a study of 144 patients with obstructive airways disease, of whom 93 had 'chronic bronchitis', the decline in FEV<sub>1</sub> was more rapid in those patients who used continuous  $\beta_2$ -agonist (or anticholinergic) treatment than in those whose therapy was used on demand, the difference in FEV<sub>1</sub> decline between the groups being 52 mL/year [668]. This study from The Netherlands has been criticized because of the difficulty in differentiating this group from asthmatics. There is also recent evidence showing that the rebound airway responsiveness and bronchoconstriction that may occur after cessation of regular bronchodilator therapy in asthmatics does not occur in patients with COPD [669].

Very limited information is available on the effects of long-acting  $\beta_2$  agonists in patients with COPD [670–674]. In the studies that were randomized and placebo controlled there was an improvement in symptoms, quality of life and a small improvement in spirometry, without any significant change in exercise capacity [670,672,673]. Until further information is available these drugs should be restricted to those patients with a demonstrable bronchodilator response to  $\beta_2$  agonists and their use monitored in terms of symptoms. There is little evidence to support the use of sustained-release oral  $\beta_2$  agonists in patients with COPD.

### Anticholinergics

Anticholinergic drugs (see Chapter 9) have been used to treat airways obstruction for some time [675]. The side-effects from the older anticholinergic drugs such as atropine, which limited their use, was overcome by the development of an inhaled quaternary ammonium salt of atropine, ipratropium bromide, that was poorly absorbed [676]. A derivative of ipratropium bromide, oxitropium bromide, has become available in Europe and Japan [677]. Ipratropium bromide, like the  $\beta_2$  agonists, affects both central and peripheral airways [678,679] and also reduces FRC significantly [654]. Anticholinergics have a time to peak effect of 30–60 min in most COPD patients, which is slower than  $\beta_2$  agonists, but have a somewhat longer time of effectiveness (6–10 h) compared with  $\beta_2$  agonists [676]. Tiotropium bromide is a newly developed anticholinergic agent that appears to have a longer time course of action than ipratropium [680].

Optimal bronchodilatation appears to occur with 80  $\mu\text{g}$  of ipratropium and 200  $\mu\text{g}$  of oxitropium bromide [681,682]. Studies comparing 200  $\mu\text{g}$  of oxitropium bromide with 80  $\mu\text{g}$  of ipratropium bromide suggest no difference in the peak or duration of bronchodilatation [682]. Thus 80  $\mu\text{g}$  of ipratropium should be used in patients with COPD rather than the customary 40  $\mu\text{g}$  in order to produce maximum effect [683].

There is conflicting evidence regarding the effects of ipratropium bromide on exercise in patients with COPD. Some studies found an increase in maximum exercise, ventilation and a reduction in oxygen consumption at any given workload with both ipratropium bromide [684] and oxitropium bromide [685]. Studies of walking distance have also been variable. Other studies showed no improvement after ipratropium [664] or a significant improvement 45 min after 200  $\mu\text{g}$  of ipratropium in patients with COPD [686]. There is no evidence to suggest tachyphylaxis to either ipratropium or oxitropium [677,687]. The recently reported Lung Health Study in a large group of patients with COPD showed that treatment with ipratropium bromide produced a small but significant beneficial effect on  $\text{FEV}_1$  during treatment but had no

other effect on the decline in  $\text{FEV}_1$  over a 5-year period [37].

Clinical studies of anticholinergic drugs show that they are at least as efficacious as  $\beta_2$  agonists in patients with COPD [663]. Some studies report a more prolonged bronchodilator response than with the  $\beta_2$  agonists [657,688].

### Theophyllines

The bronchodilator effect of theophyllines (see Chapter 9), or methylxanthine derivatives, is modest in patients with COPD [689,690]. Their effect on symptoms and exercise tolerance is variable [691–693] and often occurs at the top of the therapeutic range. Long-term treatment with theophyllines is limited to the oral route, resulting in a slower onset of action compared with inhaled bronchodilators; thus theophyllines should only be used for maintenance therapy in oral form. There has been considerable improvement in the pharmacokinetics of oral theophyllines with the production of long-acting formulations with a half-life of 12–18 h [689,690].

The bronchodilator action of theophyllines is relatively limited in patients with COPD [689–693]. Changes in exercise tolerance in patients with COPD following theophylline treatment have been variable, either showing no improvement [691–694] or only a small improvement in either corridor or treadmill exercise [695,696]. Some of the improvement in exercise tolerance has been thought to result from the beneficial effect of theophyllines on respiratory muscles [692] or a fall in trapped gas volume [693,696], although these mechanisms are still the subject of debate. Other non-bronchodilator effects of theophylline, such as improving right ventricular performance [697] and their anti-inflammatory actions [658], are of questionable clinical significance.

Theophyllines have a narrow therapeutic index and patients often experience side-effects within the therapeutic range [698]. Other factors common in COPD, such as smoking, hypoxaemia and infection, all alter theophylline clearance and therefore make the control of dosage difficult, requiring measurement of plasma theophylline levels (Table 23.9). Thus, the possible beneficial effects of theophyllines have to be balanced against their potential side-effects in individual patients and the fact that similar benefit may be achievable with inhaled bronchodilators. This has resulted in theophyllines being reserved for patients in whom other treatments have failed to control symptoms adequately.

### Combination therapy

Studies of combination therapy are difficult to assess due to problems of suboptimal dosing. Some studies suggest that combining drugs, such as salbutamol and ipratropium [664] or salbutamol and aminophylline [695], pro-

**Table 23.9** Theophylline metabolism in COPD.

Increased by	Decreased by

	Cimetidine (not ranitidine)
	Viral infections
	Old age*

Many factors influence theophylline metabolism and those posing particular problems in COPD are indicated by asterisks, the number of these indicating the likely hazards.

duces improvement in exercise tolerance in the face of trivial changes in spirometry. It is unclear whether higher doses of salbutamol could have achieved a similar effect. Thus, combinations of bronchodilator drugs should only be used if single drugs have been tried and have failed to give adequate symptomatic relief. Combination therapy should only be continued if there is good subjective or objective benefit.

**Drug-delivery devices**

Compliance with inhaled treatment is poor. In the Lung Health Study the overall compliance with therapy was 65% [699]. Since many patients with COPD are elderly, the difficulties encountered with standard metered dose inhalers are exaggerated. These problems can often be overcome by dry powdered formulations or by a spacer device. Patients with severe COPD are only able to achieve low inspiratory flow rates; flow rates as low as 40 L/min may cause failure of the one-way valve in a spacer device to open.

**Home nebulizer therapy**

There is still controversy over the use of home nebulizer therapy in patients with COPD [700]. Using end-points such as spirometry and corridor walking exercise, it has been shown that nebulized salbutamol is no more effective in patients with COPD than lower doses of the same drug given through a spacer device [701]. However, patients appear to prefer nebulized bronchodilator therapy. This may be due to the fact that the total dose of the drug delivered by nebulizer therapy is higher, and because the facial cooling that occurs with the nebulized solution itself may have an effect on dyspnoea independent of any effect on airway calibre [702].

Although those patients who show a response in routine nebulized bronchodilator testing would seem to be the obvious candidates for this therapy, acute improve-

ment in spirometry does not necessarily predict a long-term response [702–705]. Only a minority of patients are likely to obtain benefit from high-dose bronchodilator therapy [692]. Since comparative clinical trials of metered dose inhaler and nebulized bronchodilators in COPD are inconsistent [706,707], the BTS guidelines recommend that patients should only be supplied with a nebulizer if they have been fully assessed by a respiratory physician able to assess the risk–cost benefit [708]. This assessment should include ensuring that optimal use is made of a simple metered dose inhaler or dry powdered device and that some assessment is made of the patient’s response to nebulizer therapy. It has been suggested that a formal assessment of efficacy should include a home trial with PEF measurements. It is essential that adequate technical support and follow-up is available whenever a home nebulizer is prescribed. Dosage regimens need to be tailored to individual patient needs and drug side-effects monitored. This is discussed in detail in the BTS guidelines for nebulizer therapy [708].

**Corticosteroids**

Chronic inflammation in the large and small airways is a characteristic feature of COPD. This inflammatory process provides a rationale for the use of corticosteroids in this condition. However, the use of corticosteroids (see Chapter 9) in patients with COPD remains contentious, particularly the prediction of which patients will respond to this treatment.

**Oral corticosteroids**

There are several short-term studies of the effect of oral corticosteroids on airways obstruction in patients with COPD [709–715]. However, relatively few controlled studies have been undertaken [711–715] and the results of these randomized controlled trials are conflicting. Clearly, a subgroup of patients do respond to corticosteroids, and the response may continue beyond the standard 14 days of treatment [550]. A meta-analysis of trials of oral corticosteroids indicates that a significant improvement in FEV<sub>1</sub> (>15% and >200 mL improvement in FEV<sub>1</sub>) occurs in 10–20% of patients with clinically stable COPD [710]. There are no reliable predictors of which patients will respond. Indeed, in one study the presence or absence of clinical features of emphysema did not affect the response rate [716]. In contrast to asthma, corticosteroids do not affect the bronchial hyperresponsiveness that occurs in patients with COPD [717]. Furthermore, the response to high doses of oral prednisolone in short-term studies does not necessarily predict continued FEV<sub>1</sub> response to long-term inhaled steroids, although the studies on this subject are limited [665,713]. In one double-blind study in 18 patients with COPD [717], the addition of 400 or 1600 µg of inhaled budesonide daily permitted a reduction of

approximately 6.5 mg of prednisolone per day without altering the FEV<sub>1</sub>. This suggests that 400 µg daily of an inhaled corticosteroid should be adequate in patients with COPD. The follow-up period of this study was only 7 months and extrapolation to long-term effects requires further study. Data from uncontrolled retrospective studies of oral corticosteroids suggest that long-term treatment may slow the decline in FEV<sub>1</sub> [718,719]. However, the relationship between the inflammatory changes in patients with COPD and the degree of airflow limitation or indeed their response to treatment is poor [712,713]. In general, long-term oral corticosteroid treatment in COPD cannot be recommended in view of adverse side-effects.

### Inhaled corticosteroids

Short-term studies of inhaled corticosteroids given over a period of 3–12 weeks [128,551,720–722] have in general been disappointing, and have shown no change in the level of airways obstruction as assessed by FEV<sub>1</sub> or peak flow or indeed in the degree of airway responsiveness to histamine. However, two studies [551,721] indicate that a subpopulation of patients with COPD do show a response and indeed in one study inhaled steroids had a significant effect on markers of inflammation, particularly on albumin levels in BAL, reflecting an improvement in epithelial permeability [721]. There is only one study of the long-term effects of inhaled corticosteroids [723] in a group of patients who had previously shown a rapid decline in respiratory function when they did not use inhaled steroids [668]. In this study, 800 µg of beclometasone daily improved the FEV<sub>1</sub> after bronchodilator significantly during the first 6 months of treatment. However, a fall in FEV<sub>1</sub> continued over the next 6 months, indicating to the authors that longer-term follow-up was required. These effects were shown in a group characterized as COPD and in another group characterized as asthmatics, although the overlap between the two groups was significant. A long-term follow-up study [724] over a period of 2.5 years in a group of patients with both asthma and COPD also showed a beneficial effect on the number of exacerbations in both groups of patients. The limited information available suggests that there is no modifying effect of corticosteroids on the action of bronchodilators [720].

On presently available evidence, inhaled corticosteroids in doses of 1000 µg of beclometasone, 800 µg of budesonide or 500 µg of fluticasone should be given to those patients who show a response to either oral or inhaled corticosteroids. Those who do not respond should *not* be given maintenance therapy. The effects of long-term inhaled corticosteroids in COPD is currently under examination. So far the results of one large trial imply that abstinence from tobacco is likely to be more effective in reducing the rate of decline in FEV<sub>1</sub> than regular budesonide 400 µg twice daily, which had no significant effect on

the overall rate of decline or indeed symptom scores or the number of exacerbations [725].

### Other therapeutic agents

There is no evidence to support a role for anti-inflammatory drugs such as sodium cromoglycate, nedocromil sodium or antihistamines in patients with COPD. Although used widely in continental Europe, mucolytic drugs are rarely used in the UK.

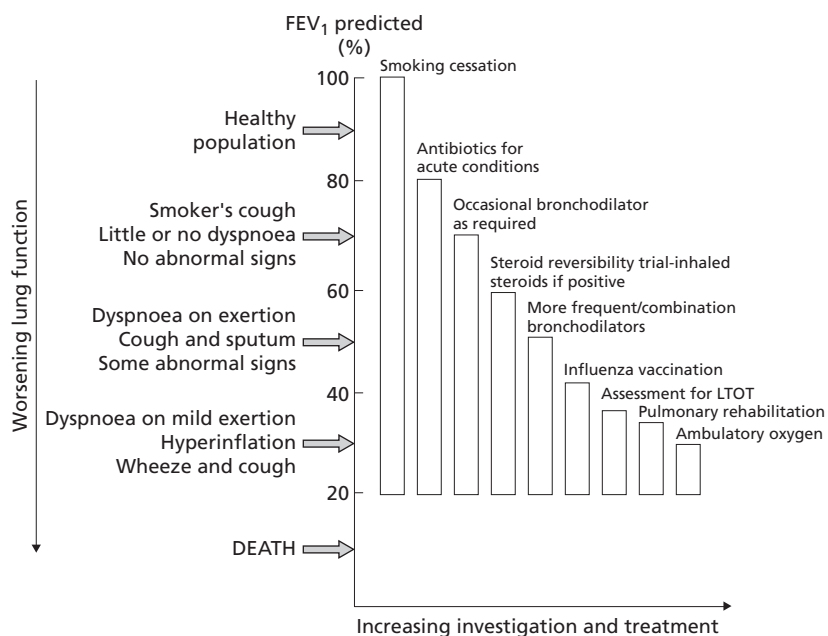

### An approach to the management of patients with COPD

The BTS guidelines suggest an approach to the management of patients with COPD based on severity of disease [4] (Fig. 23.18). COPD can be arbitrarily divided into patients with mild, moderate and severe disease based on the percentage predicted FEV<sub>1</sub>. In those with mild disease (FEV<sub>1</sub> 60–69% of predicted), stopping smoking and, in symptomatic patients, a trial of inhaled β<sub>2</sub> agonists or an anticholinergic, taken as required, may be useful. There is no convincing evidence at present that any other treatment, such as inhaled corticosteroids, affect the long-term progression of COPD. Exercise should be advocated and patients who are overweight encouraged to lose weight with the appropriate dietary advice.

In those with moderate disease (FEV<sub>1</sub> 40–59% of predicted), stopping smoking is the single most important way of affecting the outcome and this is particularly important in those who have already shown evidence of an accelerated decline in FEV<sub>1</sub>. These patients show some benefit from bronchodilator use and thus a reversibility test to a bronchodilator should be obtained, both to determine those patients who show a large degree of reversibility and therefore have asthma and because the FEV<sub>1</sub> after bronchodilator is a good predictor of survival. Unfortunately, single-dose reversibility tests do not predict which patients will have long-term symptomatic benefit from bronchodilator therapy. The effect of bronchodilator therapy should be monitored in terms of lung function or subjective symptomatic improvement.

In patients with severe disease, the severity of airflow obstruction cannot be predicted from symptoms or signs [516]. Measurement of the FEV<sub>1</sub> is the only reliable guide to severity. Reversibility tests to nebulized bronchodilators and corticosteroids should be assessed, since even patients with severe airflow obstruction can demonstrate reversibility. Those patients who show a bronchodilator response are more likely to respond to a trial of oral inhaled corticosteroids. Those who show a positive response to oral steroids should be continued on inhaled steroids.

More detailed measurements of respiratory function, such as lung volumes, transfer factor for carbon monoxide (Tl<sub>CO</sub>) or tests of pulmonary mechanics, are not routinely

**Fig. 23.18** The chronic obstructive pulmonary disease escalator: as lung function declines the treatments need to be increased. LTOT: long-term oxygen therapy.

indicated in these patients but may be useful in some cases. In these patients, hypoxaemia and hypercapnia are common and arterial blood gases should be considered in all patients with severe disease. Pulse oximetry may be useful in assessing arterial oxygenation and obviate the need for blood gas measurements if the  $SaO_2$  is greater than 92%. However blood gas measurements are obligatory for the measurement of  $Paco_2$  and in patients who are clinically deteriorating or who develop complications.

Even in the group of patients with severe disease smoking cessation should be encouraged, since it results in a more gradual deterioration in  $FEV_1$  and improves the chances of a beneficial effect of long-term oxygen therapy (LTOT) (see below). Bronchodilator therapy and corticosteroid therapy should be given as for patients with moderate disease. It is common for patients with severe COPD to receive nebulized therapy at the general practitioner's request. The prescription of nebulizers in this group remains controversial. Most patients can be managed using metered dose inhalers with spacer devices or dry powder devices. There is no evidence to support the use of continuous or intermittent prophylactic antibiotics in patients with COPD.

### Domiciliary oxygen therapy

Two landmark multicentre trials, the Medical Research Council (MRC) trial [150] and the nocturnal oxygen therapy trial (NOTT) [149], have shown improved survival with domiciliary oxygen therapy when given for at least 15 h daily (Fig. 23.19). The design of these two studies differed. The MRC study compared patients receiving 15 h

of oxygen daily with a control group who received no oxygen, whereas the NOTT compared continuous oxygen therapy (averaging 17.7 h of oxygen daily) with overnight oxygen therapy (12 h daily). Although the patients in the two studies had similar spirometry and  $PaO_2$ , the patients in the MRC study were hypercapnic (mean  $Paco_2$  7.3 kPa, 55 mmHg), whereas those in the NOTT trial were largely normocapnic ( $Paco_2$  5.7 kPa, 43 mmHg). The major outcome was an improved survival in patients receiving oxygen therapy for at least 15 h daily, although survival in the MRC group receiving 15 h daily was only significantly increased after 500 days had elapsed.

In addition to the improvement in survival, a number of studies have examined the effects of supplementary oxygen therapy and exercise tolerance. Several studies have shown an improvement in exercise endurance in patients with COPD breathing supplemental oxygen, associated with a reduction in ventilation at a given submaximal work rate and an improvement in walking distance and in ability to perform daily activities [726–729]. The effects of oxygen therapy on breathlessness remain unclear. Some studies have shown a reduction in dyspnoea scores during submaximal exercise in patients given oxygen therapy [726,728]. However, controlled trials using supplementary oxygen vs. compressed air have shown conflicting effects on breathlessness [727,729].

Assessment of patients taking part in the NOTT study showed that they had marked disturbances in mood and quality of life [514]. After 6 months of oxygen therapy, 42% of patients showed evidence of an improvement in cognitive function but little change in mood or quality of life [730]. Further studies are required to investigate the effects of oxygen therapy on quality of life.

**Fig. 23.19** Combined data from the Nocturnal Oxygen Therapy Trial (NOTT) and the Medical Research Council trial. (From Nocturnal Oxygen Therapy Trial Group [149] and Medical Research Council Working Party [150] with permission.)

The reasons for the improvement in survival with oxygen therapy in patients with COPD are still unclear. The NOTT reported a reduction in pulmonary arterial pressure on exercise after 6 months with either continuous or nocturnal oxygen therapy, and also a small improvement in pulmonary arterial pressure at rest in the group receiving continuous oxygen therapy [149]. These changes in pulmonary arterial pressure were also reflected in the measurements of pulmonary vascular resistance. The same group also showed that survival over a period of 8 years was related to a decrease in mean pulmonary arterial pressure during the first 6 months of treatment [731]. A report in a different group of patients showed that those patients who demonstrated an acute fall in pulmonary arterial pressure of more than 5 mmHg with oxygen therapy had a better survival on LTOT than those who did not show this response [732]. However, the patients in this study were unusual, since they showed a marked decrease in pulmonary arterial pressure when breathing controlled oxygen therapy.

In the MRC trial, there was no significant improvement in pulmonary arterial pressure following oxygen therapy; however, the increase of 3 mmHg per year in pulmonary arterial pressure in the control group did not occur in the treated group [150]. From these studies, it has been suggested that an improvement in pulmonary haemodynamics may account for the improved survival with LTOT. In a group of 16 patients with COPD, Weitzenblum and coworkers [733] showed that the annual increase in pulmonary arterial pressure of around 2 mmHg per year over a period of nearly 4 years before LTOT was instituted changed to an annual reduction in pulmonary arterial pressure of 2 mmHg over a period of 31 months after the

commencement of LTOT. It has also been shown that overnight oxygen therapy, which abolishes nocturnal desaturation, also decreases pulmonary arterial pressure [734]. Although some studies have shown a relationship between the fall in pulmonary arterial pressure with oxygen, given over 24 h, and long-term survival on subsequent LTOT [732,733], this has not been confirmed in one other study [735].

Thus it is still a matter of debate whether the changes in pulmonary haemodynamics relate to the improvement in survival of patients treated with LTOT [736]. However since the changes in pulmonary haemodynamics produced by LTOT are small, it seems unlikely that these changes have a major influence on survival. Indeed Wilkinson and coworkers [228] showed continued evidence of pulmonary vascular changes in patients with respiratory failure who died despite having received LTOT.

As in all studies of patients with COPD, Cooper and colleagues [737] showed that the  $FEV_1$  was the strongest predictor of survival in patients receiving LTOT, and that LTOT did not influence the decline in  $FEV_1$  [738]. However, as in general studies in patients with COPD, the level of pulmonary arterial hypertension is also related to survival in patients who receive LTOT [739].

LTOT has also been shown to affect the polycythaemia that occurs in patients with chronic hypoxaemia, by reducing both the haematocrit and the red cell mass [150]. The clinical relevance of these haematological changes produced by LTOT remains unclear. However, continued cigarette smoking, and hence chronic elevation of carboxyhaemoglobin, decreases the effectiveness of LTOT in correcting polycythaemia [740]. The red cell mass formed

part of a complex equation for the prediction of improved survival in patients treated with LTOT in the MRC trial, and this has been used as evidence to support the contention that those who continue to smoke are less likely to have a survival benefit from LTOT [150]. Thus continued cigarette smoking should be a relative contraindication to LTOT.

### Criteria for the prescription of domiciliary oxygen therapy

There are three forms of domiciliary supplemental oxygen therapy:

- 1 long-term controlled oxygen therapy for at least 15 h daily in patients with chronic respiratory failure, conventionally called LTOT;
- 2 portable oxygen therapy for exercise-related hypoxaemia;
- 3 short-burst oxygen therapy as a palliative treatment for the temporary relief of symptoms.

It is important to realize that the criteria for the prescription of LTOT are based on the clinical parameters of those patients with COPD who showed an improved survival in the two controlled trials of LTOT [149,150]. The same criteria have been applied to other forms of chronic hypoxaemic lung disease, although the rationale for the

prescription of LTOT in these patients is not based on evidence from controlled trials. Furthermore, central to the prescription criteria is the demonstration of significant hypoxaemia in a patient with COPD breathing room air, measured when clinically stable (Table 23.10).

In the UK, the absolute indications for LTOT refer to the criteria in the patient group who have been clearly shown to have improved survival with LTOT. The relative indications are the same as the absolute indications, without the need for oedema or hypercapnia. In the USA, LTOT can be prescribed based on pulse oximetry and in patients whose  $P_{aO_2}$  lies between 7.3 and 7.9 kPa (55–59 mmHg), provided there is evidence of cor pulmonale or polycythaemia. In Australia, patients who show desaturation on exercise to a level below 90% can also be prescribed LTOT.

A community survey in the Sheffield area by Williams and Nicol [741] found that 0.3% of patients randomly sampled from general practitioners' lists had a  $P_{aO_2}$  less than 7.3 kPa (55 mmHg). From these data they suggested that around 60 000 people in England and Wales could be eligible for LTOT; the comparable figure in the USA would be 750 000. However the majority of patients receiving home oxygen therapy do not receive 15 h oxygen daily but will be receiving cylinder oxygen [742].

LTOT is usually prescribed in the UK in the form of oxygen concentrators, although a recent survey from Scot-

**Table 23.10** Prescribing criteria for long-term oxygen therapy.

#### *UK: DHSS Drug Tariff (1985)*

- 1 Absolute indications: COPD, hypoxaemia, oedema  
 $FEV_1 < 1.5$  L;  $FVC < 2.0$  L  
 $P_{aO_2} < 7.3$  kPa (55 mmHg);  $P_{aCO_2} > 6.0$  kPa (45 mmHg)  
 Stability demonstrated over 3 weeks
- 2 Relative indications: as above but without oedema or  $P_{aCO_2} > 6.0$  kPa (45 mmHg)
- 3 Palliative

#### *Europe: Report of a SEP Task Group (1989)*

- 1  $P_{aO_2} < 7.3$  kPa (55 mmHg), 'Steady-state COPD'
- 2  $P_{aO_2}$  7.3–8.7 kPa (55–65 mmHg) with additional features as in the USA (Group 2)
- 3 Restrictive disease with  $P_{aO_2} < 7.3$  kPa (55 mmHg)

#### *USA*

- 1  $P_{aO_2} \leq 7.3$  kPa (55 mmHg) (room air)  
 $SpO_2 \leq 88\%$
- 2  $P_{aO_2} \leq 7.85$  kPa (59 mmHg) with evidence of at least one of the following:  
 P pulmonale 9 > 3 mm in leads II, III or a VF  
 (pulmonary hypertension? right ventricular hypertrophy?)  
 Dependent oedema (cor pulmonale?)  
 Erythrocytosis (haematocrit > 56%)  
 Certificate of medical necessity (CMN)  
 For Group 1: annual update of CMN required  
 For Group 2: revised CMN required after 3 months

#### *Australia: Thoracic Society of Australia (1985)*

- 1  $P_{aO_2} < 7.5$  kPa (56 mmHg), COPD, right ventricular hypertrophy, polycythaemia, oedema
- 2 Desaturation < 90% on exercise
- 3 Refractory dyspnoea associated with cardiac failure

land [743] confirmed previous regional data from England and Wales that the majority of home oxygen therapy is given to patients with COPD in the form of cylinder oxygen therapy for the relief of breathlessness. In England and Wales, general practitioners can prescribe LTOT, which contrasts with Scotland, where only respiratory physicians can prescribe this treatment [744]. Data from the Liverpool area [745] indicate that adherence to the criteria for the prescription of LTOT and patient compliance is better in those patients who were prescribed LTOT by respiratory physicians. However, it is clear that even among respiratory physicians, strict adherence to the criteria in the prescription of LTOT is less than optimal, with studies reporting adherence to the criteria for domiciliary oxygen in around 40% of patients [745–747] and a mean duration of oxygen usage of around 12 h daily [742,745]. A study from Scotland by Morrison and colleagues [742], where LTOT is prescribed exclusively by respiratory physicians, showed that the majority of patients had an assessment of arterial blood gases and had established hypoxaemia. However, a major diversion from the criteria for the prescription of LTOT was that these measurements were often made when the patients were in an unstable state, often at the end of a hospital admission for an exacerbation of COPD. This raises the concern that some patients may be receiving LTOT inappropriately, since data from the NOTT study showed that 43% of patients who were initially screened and shown to fit the criteria for LTOT were no longer eligible when reassessed 4 weeks later [748], data that have been confirmed by others workers [749]. It is therefore essential that clinical stability is demonstrated, with no exacerbation of COPD for at least 4 weeks before a decision is made to prescribe LTOT, and that other treatment such as bronchodilators and inhaled steroids are optimized before the prescription of LTOT. Furthermore, reassessment is recommended to ensure that the patient remains significantly hypoxaemic and still fits the criteria for LTOT. It has been suggested that such reassessment in these very disabled patients is best done by domiciliary nursing visits and measurements of pulse oximetry [750]. Arterial blood gases are required at the follow-up clinic to ensure that adequate oxygenation is achieved while breathing oxygen. A  $P_{aO_2}$  of 8 kPa (60 mmHg) is desirable, and this can usually be achieved by nasal prongs at flow rates between 1 and 3 L/min. Precipitating an increase in hypercapnia with LTOT is seldom a problem in clinically stable patients.

### Portable oxygen therapy

In the UK, there are no established criteria for the prescription of portable oxygen/liquid oxygen therapy, although the latter is not currently available on the NHS tariff. It has been suggested that patients who desaturate during exercise by 5% or more would be suitable for portable oxygen therapy [751], although it has been shown previously that

exercise capability may improve irrespective of the arterial oxygen desaturation [728]. Portable oxygen therapy is now well established in the USA [752]. The use of portable oxygen therapy to enhance mobility should be encouraged in patients in order to help prevent the downward spiral of immobility and physical deconditioning.

Surveys have also indicated that between 10 and 20% of patients restart the tobacco smoking habit after commencing LTOT, having quit at the time of prescription [742,753]. Not only is there the theoretical problem of loss of the survival benefit of LTOT in patients who continue to smoke, but the combination of cigarette smoking and oxygen is clearly a fire hazard.

LTOT should be prescribed continuously during sleeping hours, which should reduce the rise in pulmonary arterial pressure by preventing episodes of oxygen desaturation at night [754] and also improves sleep quality [515].

### Travel

Commercial air cabins are pressurized to the equivalent of an altitude of no more than 2600 m, producing an oxygen tension of around 13 kPa (100 mmHg). Increasing hypoxaemia may worsen the symptoms of breathlessness, particularly in patients who are already hypoxaemic with a  $P_{aO_2}$  less than 9.6 kPa (72 mmHg) [755]. The airline should be contacted by letter by the patient's respiratory physician recommending the use of oxygen and most will provide oxygen throughout the flight.

### Oxygen delivery systems

In the UK, home oxygen therapy can only be supplied in the form of compressed gas cylinders or oxygen concentrators on the NHS tariff. Liquid oxygen is used in the USA and continental Europe.

The cylinders that UK pharmacists ordinarily dispense for home use are aluminium (A) F-size, containing 1360 L so that they will last approximately 11.3 h at a 2 L/min flow rate. Various other sizes of cylinder are available for purchase outside the UK NHS drug tariff, the oxygen itself being prescribable. Aluminium lightweight E-size cylinders, weighing about 6 Kg and providing about 5 h at 2 L/min, can be made portable by the provision of a purpose built cart. Smaller PD-size cylinders, containing 300 L of oxygen and providing a little over 2 h supply at 2 L/min, are much thinner and can be carried by the patient for short trips by using a shoulder strap. Oxygen concentrators are the mainstay and most convenient and cost-effective method of supplying home oxygen therapy [756]. The device contains a molecular sieve incorporating zeolite, a synthetic aluminium silicate that entraps gas molecules according to their size and polarity, and is capable of producing 96% oxygen since argon is also concentrated to about 4%. The systems are

not generally portable, although lighter versions have been developed that can produce up to 90% oxygen at 3 L/min. It is important when developing an oxygen service that there is sufficient patient education, technical support and frequent maintenance to ensure adequate oxygen delivery [757]. Oxygen concentrators become less efficient at delivering oxygen at higher flow rates [758], for example at a flow rate of 5 L/min many systems produce only 70% oxygen, although technology has improved this recently.

Generally, oxygen is delivered by means of nasal prongs, since controlled oxygen therapy is usually required. Higher flow oxygen (>35%) requires a facial mask. Inspired oxygen concentrations with nasal cannulae appear to be independent of whether the patient breathes through the nose or mouth [759], although there is clearly variability in the inspired oxygen concentration in different patients and also in the same patient from time to time [760]. Some patients are intolerant of nasal cannulae, since they complain of local irritation and dermatitis. Humidification can be supplied by the addition of a humidifier to an oxygen concentrator, although this is not normally recommended in view of the possibility of bacterial contamination. Patient compliance with masks is generally considered to be less than that with nasal prongs. In those intolerant of nasal prongs, or in whom there is refractory hypoxaemia, oxygen can be delivered tracheally in an acceptable form to patients [761,762]. Several groups have now reported their experience with transtracheal oxygen therapy [763–765] using various techniques, including a totally implanted system with tubing tunnelled beneath the skin [766]. Transtracheal oxygen can reduce the resting flow rate requirements by 25–50% compared with nasal cannulae [761,763,765] and this can result in considerable savings, particularly if liquid oxygen is the supply mode. There are complications, including the formation of mucous balls in some 25% of cases, cough, infection and catheter dislodgement [765]. In general, this form of oxygen delivery has not been very popular in the UK.

Other reservoir devices have been developed to reduce the total oxygen requirement and therefore cost, particularly if cylinder liquid oxygen is required. These systems work on the basis of a reservoir that fills during the patient's exhalation and supplies oxygen only during inspiration. These systems can reduce oxygen flow requirements by around 50% [767–769]. Other devices, including respiratory-phased, demand or pulsed oxygen delivery systems, have also been developed [770].

There is evidence that LTOT is being prescribed too late in the treatment of the disease [742] since as many as 50% of patients die in the first 3 months of LTOT. Based on this evidence, early referral to pulmonary specialists to identify the need for oxygen is appropriate.

In the UK, oxygen therapy at 15 h per day in the form

of cylinders currently costs about £6500 per annum per patient, whereas supplying an oxygen concentrator service can usually be arranged for around £1000 per annum.

## Pulmonary rehabilitation

Rehabilitation has been defined as 'the restoration of the individual to the medical, mental, emotional, social and vocational potential of which he/she is capable' [771]. An important aim of pulmonary rehabilitation is to prevent the deconditioning that occurs with lack of exercise and immobility due to dyspnoea and allow the patient to cope with the disease [772]. Before considering rehabilitation, it is vital that investigations and therapy are directed towards any reversible component of the airflow limitation and that this treatment is optimized. Patients with moderate to severe COPD should be considered for pulmonary rehabilitation programmes and each rehabilitation programme should be tailored to fit individual patients' needs, depending on the factors deemed to limit exercise [773].

### Pulmonary rehabilitation programme

Establishing a pulmonary rehabilitation programme requires a multidisciplinary approach [772] and appropriate healthcare resources. Exercise training programmes have taken two approaches. The first is to attempt to improve cardiorespiratory fitness by aerobic exercises of 20–30 min duration at least three times per week [773]. It has been suggested that this may not be the correct approach in patients with COPD, since they may be unable to achieve the required increase in oxygen uptake in order to produce the required 'training effect' because of breathlessness [774]. This approach is therefore usually restricted to those patients with mild to moderate exercise limitation. In selected groups of patients, this form of training can result in a substantial reduction in minute ventilation at equivalent submaximal workloads [775,776].

The second approach is used in those patients who are unable, because of breathlessness, to sustain sufficient exercise to improve their anaerobic fitness. In this group the target should be to improve mobility [777]. This can be achieved by providing regular exercise sessions so that patients work to their maximum tolerable ventilatory limit or, alternatively, perform exercises aimed at specific muscle training [778]. In patients with very severe COPD, there are no established guidelines for pulmonary rehabilitation programmes, but carefully supervised exercise conditioning in the hospital setting, with oxygen supplementation, should be considered in those who develop hypoxaemia during exercise. Exercise desaturation cannot be predicted from measurement of pulmonary function

[779]. There are no published data showing the effects of supplemental oxygen on exercise rehabilitation outcomes. The presence of resting hypercapnia is not a contraindication to pulmonary rehabilitation and, in one study at least, improvements in exercise tolerance following rehabilitation were similar in those with normocapnia or hypercapnia [780].

Respiratory muscle training and ventilatory-assist devices have been used to attempt to reduce ventilatory limitation during exercise [781]. Proponents of inspiratory muscle training, achieved by breathing through a resistance, suggest that it improves respiratory muscle endurance as well as exercise performance [782]. Research in this area has recently shifted away from attempts to train the inspiratory muscles using overload techniques, in order to improve exercise tolerance in COPD [781], towards investigating the role of periodic rest in the reduction of incipient muscle fatigue [783]. Meta-analysis of studies of respiratory muscle training in patients with COPD have failed to show definite evidence of benefit, probably as a result of differences in patient selection, variations in the methods of respiratory training and doubt over the role of respiratory muscle fatigue and ventilatory limitation in COPD [391,784]. Some studies have shown positive results for the use of resistive inspiratory loading during pulmonary rehabilitation, resulting in a reduction in breathlessness [785,786]. However, the changes were small and of doubtful clinical significance. However, measurements such as maximum inspiratory and expiratory pressure ( $P_{\text{imax}}$ ,  $P_{\text{emax}}$ ) have been included in pulmonary rehabilitation programmes.

It is important to evaluate the effect of a pulmonary rehabilitation programme. The outcome is usually assessed by measuring improvement in lung function or exercise tolerance. However, benefit may not always be apparent in these variables [777,787]. In general, the results of studies of pulmonary rehabilitation show a favourable effect on exercise tolerance [788,789] and a reduction in symptoms such as breathlessness during exercise [790]. Since social factors contribute to the disability in COPD [791], assessment of quality of life should be included in a rehabilitation programme and can be measured by a health profile questionnaire [787]. It is important also to assess compliance and the longevity and cost-benefit of any pulmonary rehabilitation programme.

Education of patients to enable them to understand the various components of their disease seems intuitively valid [792]. However, studies have failed to show any significant impact of an education programme alone on symptoms, daily activity or quality of life [793,794]. Nevertheless, a controlled trial of education plus pulmonary rehabilitation has shown very encouraging effects on exercise tolerance [795].

Mood disturbances, particularly depression, are very

common in patients with advanced disease [796] and often contribute to an enhanced perception of symptoms, particularly breathlessness, and to social isolation. Antidepressant drugs can often produce encouraging results in these patients [797].

### Exercise training

Expiratory flow rates during tidal breathing in patients with severe COPD are close to the maximum expiratory flow-volume relationships [798]. Thus an increase in expiratory flow rate can occur during exercise in patients with COPD through dynamic hyperinflation [799] but at the expense of an increase in inspiratory work, since tidal volume operates in a less compliant range of the pressure-volume relationship and hence initiation of inspiration requires additional inspiratory pressure to overcome the increased elastic recoil of the respiratory system [800]. Continuous positive airway pressure (CPAP) overcomes the increased recoil pressure at the end of expiration, thus reducing dyspnoea and work of breathing. One study has shown that application of CPAP (at approximately 10 cmH<sub>2</sub>O) during exercise improved breathlessness in a small group of patients [801]. Further work is required to determine the role of this form of treatment in pulmonary rehabilitation.

### Controlled breathing techniques

This form of pulmonary rehabilitation attempts to diminish breathlessness by training patients to breathe efficiently [802]. This treatment aims to:

- 1 restore the diaphragm to a more normal position and function;
- 2 decrease the respiratory rate by using a breathing pattern that diminishes air trapping and improves the respiratory duty cycle;
- 3 diminish the work of breathing;
- 4 reduce dyspnoea and allay patient anxiety.

Techniques such as pursed lip breathing have been employed and some studies have shown an improvement in blood gases [517,803]. The effects of different postures on respiratory muscle function have also been assessed [804,805]. Diaphragmatic breathing exercises have been used to improve diaphragm function and are thought to be most helpful in patients with hyperventilation [806,807].

### Nutrition

Weight loss is common in patients with COPD, particularly in those with severe airways obstruction [791]. Those patients who are less than 90% of their ideal body weight are generally considered to be malnourished. Weight loss has been associated with a higher mortality in these

patients [808]. It would therefore seem logical to give nutritional support to patients with COPD. However, studies that have addressed this issue have produced variable results. The weight gain is lost soon after cessation of nutritional support and any improvements in peripheral muscle performance and exercise capacity are also small and of short duration [397,400,401]. However, if sustained weight gain can be achieved this may improve survival [809]. The theoretical complication of carbohydrate-based diets increasing carbon dioxide production and hence hypercapnia in patients with COPD does not appear to be a problem [810]. Further studies are required before nutritional supplementation can be recommended in patients with COPD.

Obesity should be discouraged in patients with COPD in order to avoid additional strain on the cardiorespiratory system, and appropriate dietary advice should be given.

### Vaccination

Influenza vaccination is recommended for patients with COPD, although the specific evidence for this in COPD patients is lacking. The rationale relates to other studies in elderly patients, not specifically with COPD, where a 70% reduction in mortality from influenza can be demonstrated [811].

## Management of acute exacerbations

Acute exacerbations of COPD vary from a mild increase in cough, sputum and dyspnoea to a severe illness resulting in respiratory failure and often fluid retention. Although some exacerbations may be initiated by an increase in atmospheric pollution, infection is usually an important precipitating feature. Exacerbations of COPD occur on a background of established disease and are among the most common acute respiratory problems presenting to either general practitioners or hospitals. It has been estimated that in an average UK health district serving 250 000 people, exacerbations of COPD account for 340 hospital admissions per annum and 8100 general practice consultations per annum [10]. Many patients can be managed in the community. A decision whether a patient requires inpatient support is often difficult.

### Antibiotics

Infection is a common precipitating factor, although only 50% of patients with severe exacerbations with associated respiratory failure have a positive sputum culture for a bacterium [812,813]. The commonest organisms are *Haemophilus influenzae* and *Streptococcus pneumoniae* [812,814], although more recently *Moraxella catarrhalis* has also been shown to be a common pathogen [815]. However, patients with COPD are often chronically colo-

nized with common bacterial pathogens and therefore culture of one of these organisms during an acute exacerbation does not imply that this organism is responsible for the exacerbation. Some studies have demonstrated an increased antibody titre to *H. influenzae* following the exacerbation, suggesting that this organism is causally involved [816]. Viral infections have been shown to be responsible for up to 30% of all exacerbations of COPD [817]. This may well be an underestimate due to the difficulties in viral isolation. In view of the relatively limited number of pathogens, it has been considered that bacteriological examination of the sputum may not influence the management in an acute exacerbation of COPD [819], although this is controversial [819].

There is very limited information from controlled trials on the effects of antibiotics in exacerbations of COPD [820,821]. In a small study of 40 patients requiring hospitalization for an exacerbation for COPD, there was no difference in outcome between placebo and tetracycline given for 1 week [821]. In a much larger trial of 362 exacerbations of COPD in 173 patients, the patients received a 10-day course of sulfamethoxazole (sulphamethoxazole), amoxicillin (amoxycillin), doxycycline or placebo [820]. Relief of symptoms within 21 days was achieved in 68% of the antibiotic-treated group and in 55% of the placebo-treated exacerbations. Peak expiratory flow recovered faster in the antibiotic-treated group, although the differences were small. Treatment failures were twice as common in the placebo group compared with the antibiotic-treated group. The difference in successful outcome between the antibiotic and placebo was significant if two of the following were present: increase in dyspnoea, increase in sputum volume, increase in sputum purulence. Therefore, antibiotics are recommended when these symptoms are present.

In view of the limited range of bacteria present in the sputum of these patients, broad-spectrum antibiotics such as amoxicillin 250 mg three times daily or tetracycline 250 mg four times daily are usually employed. Prescription of antibiotics should take into account local bacteriological sensitivity patterns, particularly the prevalence of  $\beta$ -lactamase-positive *H. influenzae* (around 20% in most areas in the UK) and *Moraxella catarrhalis*, of which 90% are  $\beta$ -lactamase positive. If the patient is known to have previous  $\beta$ -lactamase-positive organisms in the sputum or fails to respond to amoxicillin, then co-amoxiclav should be considered. There is no justification for expensive new antibiotics, although clarithromycin is a useful first-line drug in patients with exacerbations of COPD who are hypersensitive to penicillins, and it has better activity against *H. influenzae* than erythromycin. Antibiotics should be given orally unless there is a specific indication for intravenous administration. The presence of a pneumonia on the chest film in patients with exacerbations of COPD clearly requires antibiotic therapy and should be based on guide-

lines for community-acquired pneumonia, taking into account that *H. influenzae* and *Moraxella catarrhalis* can be aetiological organisms in patients with COPD.

### Bronchodilators

Since many studies have shown that a proportion of patients with COPD have a bronchodilator response, the use of nebulized bronchodilators in acute exacerbations of COPD is always justified. Large doses of bronchodilators inhaled in nebulized form produce greater bronchodilatation and fewer side-effects than comparable oral doses [660,822]. Nebulized bronchodilators should be given as soon as possible on admission and at intervals of 4–6 h thereafter, or more frequently if required. In patients with COPD, particularly in those with an elevated  $P_{aCO_2}$ , the nebulizer should be driven by compressed air and not oxygen in order to avoid a further rise in  $P_{aCO_2}$ . Oxygen can be given by nasal prongs at 1–2 L/min during nebulization. A  $\beta$  agonist (salbutamol 2.5–5 mg or terbutaline 5–10 mg) or an anticholinergic drug (ipratropium bromide 0.5 mg) are usually given by nebulizer in severe exacerbations. When the response to either treatment alone is poor, both can be given. However, a response to a nebulized bronchodilator in an acute exacerbation does not justify long-term treatment and assessment for a home nebulizer should be made when the patient is in a stable condition as an outpatient. Several studies have shown no difference in the degree of bronchodilatation achieved when the same dose of bronchodilator is given by metered dose inhaler, with or without a spacer device, or via a nebulizer [823,824] even in patients with an acute exacerbation of airways obstruction [825]. Patients with respiratory failure have been excluded in these studies. Thus, nebulized bronchodilators are still recommended but perhaps a switch to metered dose inhaler could be considered earlier; this would have a considerable cost benefit [826].

Several studies suggest that ipratropium bromide produces the same or greater bronchodilatation in patients with COPD than  $\beta_2$  agonists [827,828]. In acute exacerbations of COPD, no difference has been shown between the two drugs given alone or in combination in nebulized form [829,830]. In most cases nebulized bronchodilators should only be necessary for 24–48 h and a change to a metered dose inhaler or a dry powder device should be made 24–48 h before discharge.

If a patient is not responding to nebulized bronchodilators during an exacerbation, intravenous methylxanthines (e.g. aminophylline 0.5 mg/kg/h) should be considered. Although the use of methylxanthines in obstructive airways diseases is under scrutiny [831], there is relatively little information on the role of theophyllines in acute exacerbations of COPD. Rice and colleagues [832] studied 28 patients who received intravenous aminophylline or placebo in a randomized double-blind trial. Over a period

of 72 h following initial hospitalization, there were no differences in spirometry, arterial blood gases or the sensation of dyspnoea between the aminophylline-treated and the placebo-treated groups. Thus, the prescription of theophyllines has no clear role in management of acute exacerbations of COPD and the possible benefits should be weighed against the side-effects, particularly in patients with COPD who have hypoxaemia and infection, are receiving antibiotics and who may smoke, all of which can affect theophylline clearance. Thus the dose must be carefully individualized (see Chapter 9) and the serum level maintained within a narrow therapeutic range (10–20 mg/L) [833]. The usual loading dose is 6 mg/kg of aminophylline with maintenance dosage of 0.5 mg/kg/h.

There is a paucity of data on the use of corticosteroids in patients with acute exacerbations of COPD and therefore the role of these drugs remains unclear. In one single randomized, double-blind, placebo-controlled study, methylprednisolone has been shown to be efficacious in patients with an acute exacerbation of COPD [834]. In this study of 44 patients, methylprednisolone (0.5 mg/kg every 6 h) produced a significant improvement in  $FEV_1$  compared with placebo over the course of 72 h. However, only percentage changes in  $FEV_1$  were given in this study and it has been criticized in view of this. More recently, Emerman and coworkers [835] studied 96 patients presenting with acute exacerbations of COPD. This study showed that there was no difference between the effects of methylprednisolone 100 mg or placebo given in addition to other treatments in patients followed up only over the first 7 h, which may have been insufficient time to detect any improvement. However, further studies of exacerbations treated with corticosteroids in the community [836] and in hospitalized patients [836a] show a positive result.

The BTS guidelines [4] suggest that, in the absence of any further data, a 7–14 day course of steroids (e.g. 30 mg prednisolone daily or 100 mg hydrocortisone i.v. if the oral route is not possible) is clinically justified in an exacerbation of COPD if:

- 1 the patient is already on oral steroids;
- 2 there is a previously documented response to oral steroids;
- 3 the airflow obstruction fails to respond to an increase in bronchodilator;
- 4 this is the first presentation of an acute exacerbation of COPD.

However, after the acute episode, it is critical that oral steroids are discontinued, unless there has been a previously demonstrable long-term effect. The effects of steroids during an acute exacerbation do not necessarily predict a later response to chronic treatment with inhaled steroids.

### Diuretics

In patients who show fluid retention as a result of respira-

tory failure and cor pulmonale, diuretics should be used with care, as they have the potential to reduce right ventricular end-diastolic volume considerably and hence cardiac output.

Anticoagulants

Pulmonary emboli are probably more common than are recognized in severe COPD. Prophylactic use of anticoagulants has not been properly assessed in exacerbations of COPD and it is difficult to diagnose pulmonary emboli where ventilation–perfusion abnormalities are often present and can lead to false-positive reports of pulmonary thromboembolic disease. Prophylactic subcutaneous heparin is often given to patients with exacerbations of COPD, particularly those who have respiratory failure.

Physiotherapy

There is very little evidence to support the use of physiotherapy to improve expectoration of secretions in patients with acute exacerbations of COPD [837,838], although some studies suggest that there is some benefit in patients producing large amounts of sputum [839,840]. Employing physiotherapy may cause worsening of blood gases [840,841]. Chest physiotherapy is a relative contraindication in patients with respiratory failure and although some patients with large volumes of sputum may benefit, it is important to monitor oxygen saturation during physiotherapy and increase inspired oxygen concentrations if there is any evidence of desaturation.

Assessment of recovery from acute exacerbations

The FEV<sub>1</sub> should be recorded prior to discharge and arterial blood gases should be checked with the patient breathing air, which gives a guide to the need for later formal reassessment for LTOT therapy. Antibiotics need not usually be given for more than 7 days.

Lung transplantation (see also Chapter 59)

Lung transplantation developed from heart–lung transplantation, which was initially indicated for pulmonary vascular diseases [842] but was subsequently extended to other pulmonary conditions [843]. However, it became apparent that many patients undergoing heart–lung transplant had received a new heart unnecessarily. With careful patient selection, improved surgical techniques to restore a viable blood supply to the bronchial anastomosis and the introduction of cyclosporin as the principal immunosuppressant, single lung transplantation, initially for patients with fibrosing lung diseases, became possible

in 1986 [844]. In 1988 double lung transplantation, with a tracheal anastomosis, was introduced [845]. However, this procedure was accompanied by more frequent problems with airway healing and was more surgically complex than heart–lung transplantation [846]. The problem of airway healing was overcome by performing two separate bronchial anastomoses [847].

It was previously considered that patients with end-stage COPD were not suitable for single lung transplantation since perfusion would be preferentially directed towards the transplanted lung because of its lower pulmonary vascular resistance, producing profound ventilation–perfusion mismatch [848]. The success of single lung transplantation, despite the presence of abnormal mechanics in the native lung, is due in part to improved patient selection, lung preservation and anaesthetic management. There are problems if residual infection is present in the native lung [849]. In addition, large bullae may still show evidence of gross overinflation in the native lung in the early postoperative period and subsequent mediastinal shift and compression of the transplanted lung. Therefore, those patients with recurrent pulmonary infection or bilateral large bullae are considered for heart–lung transplantation or bilateral sequential lung transplantation. Criteria to be considered before lung transplantation are shown in Table 23.11.

The results of single lung transplantation and bilateral sequential single lung transplantation are good [850–853]. Only 10–15% of all recipients die within the first few weeks following transplantation. This is generally due to problems with poor lung preservation, which produces alveolar damage, sepsis or both. The 1-year survival in the UK is 60–75%, with a 3-year survival of 55–60%.

The important complications leading to death are opportunistic infections and the development of oblitera-

Table 23.11 Indications and contraindications for lung transplantation.

Indications

- Age < 50 years for heart–lung transplantation or double lung transplantation
- Age < 60 years for single lung transplantation
- Patients with an estimated life expectancy of less than 18 months

Contraindications

- Malnutrition is a relative contraindication; ideally, recipients should be within 15 kg of their ideal body weight
- Recurrent or persistent pulmonary infections are a contraindication to single lung transplantation

Other considerations

- Previous thoracic surgery increases the risk of haemorrhage
- Cor pulmonale is not a contraindication to single lung transplantation
- Psychological stability is necessary
- Absence of other major organ dysfunction should be demonstrated

tive bronchiolitis. Approximately 30% of patients surviving the perioperative period subsequently develop obliterative bronchiolitis in the first 5 years after transplantation. The development of obliterative bronchiolitis leads to progressive deterioration and ultimately respiratory failure or consideration for retransplantation after 6–12 months.

## Other forms of emphysema

### Infantile lobar emphysema

Infantile lobar emphysema is obstruction and distension of one lobe in an infant and often gives rise to severe dyspnoea necessitating surgical removal. There is a strong female preponderance and about half of the cases also have congenital cardiac abnormalities [158].

### Pathology and pathogenesis

The upper lobe, especially on the left, or the middle lobe are most often affected. The lobe, or occasionally part of it, is grossly distended with thin atrophic alveoli and impinges on the neighbouring lung, often causing collapse [158]. It is thought that in some patients there is atresia of bronchial cartilage causing a ball-valve obstruction. In others, the obstruction may be inflammatory or due to mucus or a flap of mucous membrane. One study reported an increase in the deposition of collagenous tissue in the alveolar walls but no bronchial lesions in any of the seven cases studied [854]. A few cases have been described with similar clinical and radiological features in whom the pathological finding was a gross increase in the number of alveoli with or without emphysema [855]. In most patients the cause of the abnormality is obscure.

### Clinical features

Most patients with this condition develop symptoms when less than 6 weeks old, the chief manifestation being dyspnoea. The condition may prove fatal. The rest of the lung, heart, mediastinum, diaphragm and even the chest wall may be displaced or bulged out by the distended lobe. Cough and stridor may occur. A few patients have less distension and milder symptoms, which allows surgery to be withheld for several years at least.

### Treatment

Most of the acute cases require surgery. As the cause of the obstruction can seldom be identified, the lobe has to be removed. CPAP has been used in distressed patients pending surgery [856]. Follow-up of surgically and medically treated patients suggests that asymptomatic or mildly symptomatic infants do not require surgery [857].

### Lobar emphysema with bronchial atresia

This appears to be a rare variant of infantile lobar emphysema [158]. There is complete atresia of the proximal bronchus, which is blind on its hilar side but may be patent peripherally. The left upper lobe is transradiant and hypoplastic, being aerated by collateral ventilation. Most patients have been diagnosed in young adult life and are symptom free, a transradiant left upper zone on the radiograph having drawn attention to the anomaly [858].

### Unilateral emphysema of a lung or lobe due to localized bronchiolitis or bronchitis (McLeod's syndrome)

McLeod [859] was the first to draw attention to patients with a chest film showing unilateral hypertransradiancy. In these cases the pulmonary artery on the affected side is often small and pulmonary angiography shows a poor blood supply. Bronchography reveals irregular dilatation of the bronchi of about the fifth order, with failure to fill the peripheral airways, an appearance characteristic of bronchiolar obliteration [860]. Study of a number of resected lung specimens have shown evidence of previous widespread patchy bronchitis or bronchiolitis [861]. It is presumed that this dates from childhood. In some children, the condition has been shown to develop 6 months to 5 years after a viral bronchiolitis and, indeed, there is a history of such an event in more than half of the cases [862].

### Pathology

The affected lung is usually normal or subnormal in size. If an operation is performed to resect the lung, when the chest is opened the lung does not deflate. There is panacinar emphysema but also evidence that there are fewer alveoli than normal. The bronchi appear to have a full complement of branches and therefore it is thought that the causal condition must occur between birth and the age of 8 years. There is usually evidence of patchy destruction or obstruction of small bronchi and bronchioles and occasionally the larger bronchi. The pulmonary arteries often appear less hypoplastic than might be expected from the pulmonary angiogram, suggesting that there may be additional hypoxic vasoconstriction to cause the appearances on the angiogram. The pathology of the pulmonary vasculature reveals hypertrophy of the pulmonary arterial walls and a decrease in the number of branches [163].

### Functional abnormalities

There is usually some evidence of airways obstruction and an increase in RV. Bronchspirometry shows diminished oxygen uptake in the affected lung, which may be only

5 or 10% of the total for both lungs. Radioisotope ventilation–perfusion scanning shows very little ventilation or blood flow to the affected lung [860]. In some of these patients, the main bronchus may be seen bronchoscopically to collapse on expiration, but at least in one case repair of the bronchus did not improve the condition, indicating that there was also distal damage to the bronchi [163].

### Clinical features

Most patients are diagnosed on a routine chest radiograph and are often asymptomatic. In older patients, there may be coincidental chronic bronchitis. When larger bronchi are affected, secondary infection may occur that results in bronchiectasis and chronic infection.

### Radiology

Chest radiography shows unilateral hypertransradiancy with decreased vascular markings both at the hilum and in the lung (Fig. 23.20). The mediastinum may be deviated to the affected side. The diaphragm may be normal in position or low in the chest. An expiration film may show air trapping, with deviation of the mediastinum to the contralateral side. On angiography, the pulmonary artery is small and there is poor peripheral filling. Bronchograms show poor peripheral filling and dilatation of the bronchi,

with absence of the normal narrowing peripherally or with frank bronchiectasis. Most of the bronchi are irregular, terminating either in an irregular tapering shadow or in a bulbar shadow [163].

### Differential diagnosis

Unilateral changes in chest wall soft tissues, such as paralysed muscles, congenital absence of the pectoral muscles or mastectomy, may give similar appearances that are resolved by examining the patient. In compensatory emphysema, the collapsed lobe can usually be seen and the vessels in the emphysematous lobe are fanned out. It may be more difficult to differentiate this condition from the local attenuation of generalized emphysema, although in the latter the heart is often long and narrow and the hilar vessels on both sides tend to be prominent rather than diminished. Diaphragms are likely to be low and a lateral film shows the enlarged retrosternal airspace in generalized emphysema, whereas in unilateral transradiancy due to bronchiolitis the lung is usually normal or decreased in size. Occasionally, one pulmonary artery is congenitally absent, and in congenital heart disease the blood supply is sometimes very much decreased to one lung. In both of these conditions, there is no evidence of air trapping. Occasionally, hypoplasia of one lung may occur without hypertransradiancy but with a small and shrunken lung [163].

**Fig. 23.20** Chest film of an asymptomatic patient with McLeod's syndrome showing overinflated and avascular left lung.

### Prognosis and treatment

The prognosis is good since there is usually adequate reserve in the unaffected lung. Occasionally, bronchiectasis may be severe enough to warrant resection.

### Lung volume reduction surgery

The growing number of patients with emphysema on waiting lists for lung transplantation has led recently to a re-examination of surgical techniques that might give symptomatic relief, particularly the work of Brantigan in the 1950s [863]. Cooper and colleagues [864] have pioneered the technique of lung volume reduction surgery (LVRS, pneumectomy or pneumoplasty). The rationale for this technique is to reduce the volume of overinflated emphysematous lung by 20–30%, with the aim of improving the elastic recoil of the lungs, diaphragm configuration, chest wall mechanics and gas exchange. The problem of persistent air leaks after this operation was overcome by the use of strips of bovine pericardium to buttress the stapling line. The technique is usually performed via a median sternotomy, without the need for cardiopulmonary bypass. There have been no controlled trials of this technique, although Cooper argues that the results of his published series, where the patient acts as his/her own control, are sufficiently striking to obviate the need for such a trial. The initial report on 20 patients with severe COPD suggests that careful selection is necessary, on the basis of a distended thorax, predominantly upper lobe disease (demonstrated by CT) and severe functional disability despite a programme of pulmonary rehabilitation

[864]. The early results are encouraging, with no early or late deaths. The improvements that have occurred up to 6 months after surgery are impressive and are better than can be produced by conventional medical treatment with bronchodilators or corticosteroids.

Thoracoscopic laser pneumoplasty has been developed as an alternative technique to the more conventional excisional surgery. The Nd:YAG laser [865] appears to be a safer technique than the carbon dioxide laser [624] and relies on the fact that at operation the lung that remains represents the most affected areas and would absorb most energy; thus the scarring and contraction would be concentrated in these sites. Wakabayashi and colleagues [866] used a modified technique and have reported the largest series of LVRS, although follow-up data are incomplete [867] and both unilateral and bilateral procedures are reported. None the less, impressive improvements in lung function have been demonstrated. Recent case reports also suggest that LVRS may act as a bridge to lung transplantation [868].

Studies investigating the mechanism for the benefit derived from LVRS are clearly required. A recent study compared LVRS with single lung transplantation for emphysema [869]. The disease severity was greater in the lung transplantation group, and although the increase in FEV<sub>1</sub> and FVC was greater in this group, the increase in 6-min walking distance was similar in both groups.

A number of questions concerning this technique require answers from future studies, particularly knowledge of the duration of benefit, the best selection criteria for patients and the mechanism of the improvement [870].

# RESPIRATORY FAILURE

WILLIAM MACNEE

When the lungs cannot fulfil their primary function of maintaining adequate gas exchange at rest or during exercise, respiratory insufficiency or respiratory failure is said to exist. This results in an inability to maintain normal blood gases, so that the  $P_{aO_2}$  is low, with or without a rise in  $P_{aCO_2}$ , usually but not always because of lung disease. Abnormal blood gases may occur in conditions not associated with respiratory insufficiency, such as the hypoxaemia associated with anatomical right-to-left intracardiac shunts or metabolic alkalosis. Respiratory failure has been rather arbitrarily defined by Campbell as a  $P_{aO_2}$ , measured at rest at sea level, of less than 8 kPa (60 mmHg) or a  $P_{aCO_2}$  above 6.5 kPa (49 mmHg) [1,2]. This defining level of  $P_{aO_2}$  was chosen since it is close to the critical point on the oxyhaemoglobin dissociation curve below which the curve becomes much steeper, so that relatively small falls in  $P_{aO_2}$  are associated with increasingly large decreases in oxygen saturation and blood oxygen content and hence in oxygen supply to the tissues. The position of the oxyhaemoglobin dissociation curve is often characterized in terms of the  $P_{50}$ , the partial pressure of oxygen at 50% saturation.

In chronic respiratory failure, abnormal gas exchange may first occur during exercise and later at rest. During exercise in normal subjects the distribution of ventilation-perfusion ( $\dot{V}_A/\dot{Q}$ ) ratios becomes more even than at rest [3]. The alveolar-arterial  $PO_2$  difference ( $P_{AO_2} - P_{aO_2}$ ) does not widen until the oxygen uptake is very high, when the central venous oxygen content has fallen to very low levels. In patients with respiratory disorders, impairment in gas exchange characteristically leads to widening of the alveolar-arterial  $PO_2$  difference and arterial oxygen desaturation.

Although dyspnoea is a common feature of the conditions causing respiratory failure, it is not an invariable accompaniment. For example, patients with primary alveolar hypoventilation and respiratory failure may not complain of dyspnoea. Conversely, many patients can achieve adequate alveolar ventilation by virtue of increased work of breathing and thus maintain virtually normal blood

gases. Thus although they do not by definition have respiratory failure, yet they can be very dyspnoeic. This classically occurs in patients with severe emphysema and in early restrictive lung disease.

Respiratory failure may be *acute*, for example in opiate overdose, or *chronic*, with permanent blood gas disturbances as in severe chronic obstructive pulmonary disease (COPD). The major mechanisms of blood gas disturbances involve ventilation-perfusion inequality, inadequate alveolar ventilation or a combination of both. Hypoxaemia without  $CO_2$  retention is sometimes called 'type I' respiratory failure and hypoxaemia with hypercapnia 'type II' respiratory failure or ventilatory failure [4,5].

## Type I respiratory failure

In general most pulmonary and cardiac causes of respiratory failure lead to hypoxaemia without hypercapnia. This type of respiratory insufficiency is most often associated with those conditions that affect the interstitium and alveolar walls of the lungs and result in lowered values for carbon monoxide diffusing capacity and a restrictive pattern of ventilatory abnormality, e.g. fibrosing alveolitis and pulmonary oedema, but is also seen in other conditions such as pulmonary embolism and pneumonia. It may also be seen in obstructive lung diseases, such as COPD and asthma. A list of the common causes is given in Table 24.1.

In all these conditions  $\dot{V}_A/\dot{Q}$  mismatching is marked, resulting in either increased dead space and wasted ventilation (increased lung units with high  $\dot{V}_A/\dot{Q}$  ratios) or venous admixture (increased lung units with low  $\dot{V}_A/\dot{Q}$  ratios).  $\dot{V}_A/\dot{Q}$  mismatching accounts for the hypoxaemia in the great majority of cases. A similar effect on tissue oxygenation also occurs when the  $P_{aO_2}$  is normal but blood oxygen content is low, for example in anaemia, carbon monoxide poisoning and methaemoglobinemia. Hypoventilation also results in hypoxaemia. In this case total ventilation is not matched to oxygen uptake and  $CO_2$  production and in order to maintain the respiratory quo-

tient,  $P_{aO_2}$  and  $P_{aCO_2}$  fall in a ratio of 0.8. A diffusion defect causing hypoxaemia is relatively rare and occurs in normal subjects exercising at high altitude, in interstitial lung disease such as fibrosing alveolitis, particularly during exercise, and in rare cases of capillary shunting associated with liver fibrosis.

If control of ventilation is intact, as it usually is in these patients, ventilation increases in response to a raised  $P_{aCO_2}$ , so that the excess  $CO_2$  is excreted by the normal areas of the lungs facilitated by the shape of the  $CO_2$  dissociation curve. This requires that the lungs are mechanically able to respond to the increased drive. Hyperventilation cannot result in much more oxygen being taken up in the normal areas of the lungs, since the blood there is already fully oxygenated. In lobar pneumonia, for instance, where ventilation-perfusion imbalance occurs but the respiratory system can respond to an increase in  $P_{aCO_2}$  by alveolar hyperventilation, there is hypoxia but a normal  $P_{aCO_2}$ . Generally, in the restrictive disorders and asthma the ability to ventilate and maintain a normal or low  $P_{aCO_2}$  is preserved until late in the course of the disease.

Oxygen is the critical therapy in the management of type I respiratory failure and can be given with impunity in this condition since there is no hypercapnia. In severe disease, such as intractable pulmonary oedema or the adult respiratory distress syndrome (ARDS) when there is failure to maintain an adequate  $P_{aO_2}$  on high-flow oxygen ( $P_{aO_2} < 8 \text{ kPa}$ , 60 mmHg) or when hypercapnia ensues, ventilatory support is required.

## Type II (hypercapnic) respiratory failure

When the  $P_{aCO_2}$  rises due to alveolar hypoventilation, the

$P_{aO_2}$  must fall; knowing one of these values, the other may be predicted using the alveolar air equation. Some causes of alveolar hypoventilation are listed in Table 24.2. The most common cause is COPD, which may result in acute to chronic hypercapnic (type II) respiratory failure that usually occurs during an acute exacerbations of this condition.  $CO_2$  retention in COPD is unusual when the forced expiratory volume in 1 s ( $FEV_1$ ) is greater than 1.2 L [6] (Fig. 24.1). Type II respiratory failure due to alveolar hypoventilation alone can occur in such conditions as poliomyelitis, polyneuritis, myasthenia gravis, sedative drug overdose, cerebrovascular accidents, chest injury and acute oedema of the larynx. If respiratory failure is of sudden onset, the acute rise in  $P_{aCO_2}$  results in a rise in hydrogen ion concen-

tration (a fall in pH). Respiratory failure that develops slowly allows renal compensation with retention of bicarbonate, often resulting in a near-normal pH. The presence of a raised bicarbonate therefore suggests acute-on-chronic respiratory failure, most commonly caused by an exacerbation of COPD. Suspicion of respiratory failure should immediately lead to blood gas determination since the clinical findings are often unreliable.

## Clinical features

### Clinical evidence of hypoxaemia

Hypoxaemia results in central cyanosis that is best assessed by examining the oral mucous membranes, since blood flow at this site is well maintained when the periphery may be vasoconstricted. The relationship between cyanosis and hypoxaemia is notoriously variable and there is wide interobserver variation [7,8]. Cyanosis is more easily observed in polycythaemic patients, whereas in anaemic patients there may be insufficient reduced haemoglobin to produce a blue colour to the mucous membranes.

Hypoxaemia affects the central nervous system (CNS) at an early stage, with the development of irritability, impaired intellectual function and clouding of consciousness. This may progress to convulsions, coma and death. A level of acute hypoxaemia that would kill a previously healthy individual may be surprisingly well tolerated by patients with chronic hypoxia. Hypoxaemia stimulates ventilation via the carotid chemoreceptors, increases the heart rate and cardiac output and dilates peripheral vessels. Cardiac dysrhythmias may occur, which may be exaggerated by concomitant digitalis or hypokalaemia due to diuretic therapy [9]. The pulmonary arteries respond to hypoxia by vasoconstricting, producing increased vascular resistance and pulmonary hypertension, with the later development of right ventricular enlargement or cor pulmonale.

Persistent hypoxia results in secondary polycythaemia due to increased production of erythropoietin. There is some evidence that cigarette smoking, with a resultant elevation of carboxyhaemoglobin levels, also contributes to the development of polycythaemia in hypoxaemic patients [10].

### Clinical evidence of hypercapnia

The lowest level of  $P_{aO_2}$  compatible with life is approximately 2.7 kPa (20 mmHg) [11,12]. Since there is a relationship between the fall in  $P_{aO_2}$  and the rise in  $P_{aCO_2}$ , and because patients with COPD have an increased alveolar-arterial oxygen gradient,  $P_{aCO_2}$  rarely exceeds 10.6 kPa (80 mmHg) in these patients when breathing room air [12]. The CNS effects of hypercapnia are variable

from patient to patient. There is a poor correlation between  $P_{aCO_2}$  and the development of these effects, as changes in  $P_{aCO_2}$  may be more important than the actual level. The CNS signs of hypercapnia are irritability, confusion, somnolence and coma [13,14]. Coma is uncommon in patients with COPD and respiratory failure when breathing room air because the level of  $P_{aCO_2}$  necessary to cause coma is usually associated with a  $P_{aO_2}$  incompatible with life [15]. The level of consciousness correlates with the cerebrospinal fluid pH, which itself is decreased in proportion to the blood pH level [16]. The rapidity of the increase in  $P_{aCO_2}$  and the severity of the associated hypoxaemia also contribute to the level of consciousness [17]. Acidemia itself can clearly contribute to the degree of impairment of consciousness, since levels of  $P_{aCO_2}$  up to 14.6 kPa (110 mmHg) have been noted in the absence of acidemia without producing obvious CNS signs [18]. Hypercapnia also produces tremor, myoclonic jerks, asterixis and even seizures [13]. The vasodilator properties of  $CO_2$  may result in increased cerebral blood flow and an increase in intracranial pressure, producing headache and papilloedema [14,18–21]. Hypercapnia tends to dilate the vessels of the peripheral circulation by a direct effect on vascular smooth muscle, but also produces vasoconstriction by sympathetic stimulation. Both the vasodilator properties and sympathetic stimulation produced by  $CO_2$  result in a warm flushed skin with a bounding pulse [17,22]. However, the resultant effect in an individual depends on the balance between the two and is variable. Sympathetic stimulation is also responsible for tachycardia and sweating. Marked hypercapnia, producing generalized vasodilatation, may be associated with hypotension. Other features occasionally encountered in severe and well-established respiratory failure are gastric dilatation and paralytic ileus. Headache on waking is common in chronic hypercapnia, presumably due to a progressive increase in  $CO_2$  retention during sleep.

Three major mechanisms contribute to hypercapnic ventilatory failure: (i) insufficient respiratory drive; (ii) excessively high ventilatory workload; and (iii) defective ventilatory pump or 'bellows'. There are many potentially reversible factors that may affect ventilatory drive and these include the use of sedatives, chronic loading of ventilation as in a prolonged asthmatic attack, and metabolic alkalosis. The ventilatory workload is related to the level of  $CO_2$  production, the ventilatory dead space, the pulmonary resistance or compliance and the need to compensate for a metabolic acidosis. Increased  $CO_2$  production also occurs in conditions associated with increased metabolism, as in patients with burns, sepsis or fever and in hypercaloric carbohydrate parenteral feeding [21].

The dead space comprises the anatomical and alveolar (physiological) dead spaces. Increases in dead space result in 'wasted ventilation'. In patients with emphysema, an

increase in dead space primarily results from enlargement of the anatomical dead space as a result of enlargement of distal airspaces. Increased alveolar dead space ventilation also occurs with changes in the breathing pattern, such as an increasing respiratory rate. Increased wasted ventilation also occurs in patients with pulmonary emboli or other conditions that produce occlusion of the pulmonary arteries or capillaries.

Bellows or pump failure is a less common cause of ventilatory failure and may occur in patients with neuromuscular diseases and severe impairment of phrenic nerve function. Patients with neuromuscular diseases characteristically breathe with rapid shallow tidal volumes. Orthopnoea is a frequent symptom especially in the presence of diaphragmatic or bilateral phrenic nerve involvement. The development of tachypnoea often maintains normal blood gases until respiratory reserve is markedly diminished. Thus repeated evaluation of patients with neuromuscular diseases is necessary to anticipate the development of ventilatory failure. Bedside spirometry, the prevention of atelectasis and taking precautions against aspiration can be helpful. Ideally patients at high risk are identified before complications develop and are intubated electively.

## Diagnosis

The diagnosis of respiratory failure rests on measurement of arterial blood gases. The conventional definition of res-

piratory failure is a  $P_{aO_2}$  when breathing air at sea level of less than 8 kPa (60 mmHg) [1,2], although in some studies a  $P_{aO_2}$  of less than 7.3 kPa (55 mmHg) is used [5]. Since mixed metabolic and respiratory acid-base disturbances can occur, and because a rise in  $P_{aCO_2}$  is a normal compensatory response to a metabolic alkalosis [23,24], it is important to measure the arterial pH or to determine the primary acid-base disturbance. In addition, the chronicity of the respiratory failure should be assessed by evaluating the pH and the degree to which this is compensated by an increase in the serum bicarbonate. An acute increase in  $P_{aCO_2}$  of 1.3 kPa (10 mmHg) is roughly associated with a decrease in pH of 0.08 units and an increase in serum bicarbonate of 1 mEq/L, whereas a chronic increase in  $P_{aCO_2}$  of 1.3 kPa (10 mmHg) is associated with a decrease in pH of 0.03 units and an increase in bicarbonate of 3.5 mg/L [25,26]. Plotting blood gas and acid-base parameters on an acid-base diagram is a useful way of determining the acid-base status and also following the response to treatment in patients with acute exacerbations of COPD and respiratory failure [4] (Fig. 24.2).

As indicated above, the  $P_{aO_2}$  has to be at a very low level to threaten life. Indeed, in a study of patients presenting with acute-on-chronic respiratory failure, the level of hypoxaemia when breathing air on admission did not relate to survival during the acute episode [27,28]. A relatively modest increase in  $P_{aO_2}$  is all that is required when treating such patients with oxygen. However, when supplemental oxygen is given to patients with COPD in acute

**Fig. 24.2** A non-logarithmic acid-base diagram derived from the measured acid-base status of patients within the five abnormal bands illustrated and of normal subjects (hatched box). This plot of  $P_{aCO_2}$  against hydrogen ion concentration (pH) allows the likely acid-base disturbance and calculated bicarbonate value (obtained from the relevant isopleth) to be rapidly determined, while changes during treatment can be plotted serially for each patient. (After Flenley [4] with permission.)

respiratory failure, a proportion of these patients show a rise in  $P_{aCO_2}$ . In one study, approximately one-third of patients showed a rise in  $P_{aCO_2}$  of greater than 0.5 kPa (3.75 mmHg) when given controlled (24–28%) oxygen therapy, one-third did not show this rise and one-third showed a fall in  $P_{aCO_2}$  [28]. Thus even controlled oxygen therapy can produce some  $CO_2$  retention [11]. Traditionally, this is thought to result from the dependence of COPD patients on their hypoxic drive to breathing and the fact that their ventilatory response to  $CO_2$  is also believed to be impaired [11]. Thus, removal of the hypoxic drive to breathing with supplemental oxygen is thought to result in a fall in minute ventilation and a rise in  $P_{aCO_2}$ . Furthermore the blunted  $CO_2$  responsiveness prevents a subsequent increase in minute ventilation. However, experimental studies do not support this hypothesis.

In patients with respiratory failure, Aubier and coworkers [29] found that the rise in  $P_{aCO_2}$  when breathing 100% oxygen could not be accounted for by the fall in minute ventilation. These authors attributed the increase in  $P_{aCO_2}$  primarily to an increase in the dead space to tidal volume ratio ( $V_D/V_T$ ), although this contention remains controversial [30]. Measurements of the mouth occlusion pressure ( $P_{0.1}$ ), an index of central respiratory drive, are increased in patients with acute respiratory failure [31]. Furthermore,  $P_{0.1}$  fell when supplemental oxygen was given but the values still remained higher than those obtained in patients in the chronic state. Recent studies in ventilator-dependent patients with COPD suggest that hyperoxia produces both a decrease in respiratory drive and an increase in  $V_D/V_T$ . In addition, correction of hypoxaemia shifts the  $CO_2$  binding curve (the Haldane effect), which increases  $P_{aCO_2}$  for a given  $CO_2$  content. Thus, it is likely that the mechanism by which oxygen supplementation worsens hypercapnia is multifactorial [32].

## Management

The priorities in the management of acute respiratory failure vary according to the aetiology. The primary aims of treatment are the same in all cases: (i) to maintain a patent airway and ensure adequate alveolar ventilation and oxygenation; and (ii) to treat, if possible, the primary condition.

Transplantation in the management of respiratory failure is dealt with in Chapter 59.

### Type I respiratory failure

This condition usually presents little difficulty and, apart from the use of oxygen, treatment of the primary cause, e.g. antibiotics for lobar pneumonia, may be all that is required.

Arterial hypoxaemia when extremely severe can be life-threatening and therefore should have the highest priority when managing acute respiratory failure. The goal should be to increase saturation of haemoglobin to at least 85–90% without risking significant oxygen toxicity. As a general rule, very high  $F_{IO_2}$  levels can be safely used for brief periods of time while efforts are being made to reverse the underlying process. The use of positive end-expiratory pressure (PEEP), changes in position, sedation and paralysis may be helpful in lowering  $F_{IO_2}$ . Fever, agitation, over-feeding, vigorous respiratory activity and sepsis can all markedly increase  $\dot{V}O_2$ . Measures should be taken to eliminate these stimuli.

It is important to remember that oxygen delivery is calculated as the product of oxygen content and cardiac output. It is therefore possible to treat hypoxaemia not only by raising the inspired oxygen concentration but also by increasing the cardiac output or increasing haemoglobin concentration with packed red blood cells.

Prolonged exposure to high concentrations of oxygen ( $F_{IO_2} > 50\%$ ) should be avoided because pulmonary toxicity depends on both the duration of treatment and the  $F_{IO_2}$  [33]. If an  $F_{IO_2}$  of 50% fails to produce a  $P_{aO_2}$  of 6.7 kPa (50 mmHg), this implies a significant interpulmonary shunt, as occurs in ARDS. The major question in patients with type I respiratory failure is when to begin assisted ventilation. This obviously depends on the clinical situation. However, the general indications for ventilation are as follows:

- 1 inadequate oxygenation despite an increasing  $F_{IO_2}$ ;
- 2 increased  $P_{aCO_2}$  associated with decreased mental status or increasing fatigue;
- 3 failure to control secretions.

### Type II (hypercapnic) respiratory failure

In the UK by far the commonest cause of type II or hypercapnic respiratory failure is an exacerbation of COPD. Indeed 'respiratory failure' is frequently regarded as synonymous with this condition.

#### Natural history of respiratory failure in patients with COPD

The development of arterial hypoxaemia occurs insidiously in most patients with COPD, although in some the fall in  $P_{aO_2}$  can be as rapid as 1 kPa (7.5 mmHg) per year. In the industrial city of Sheffield, where both occupational exposure and the prevalence of smoking are high, it has been estimated that 0.3% of the population over the age of 45 have arterial oxygen tensions of less than 7.3 kPa (55 mmHg) [34]. Hypoxaemia that develops slowly may produce little in the way of breathlessness and chronic hypercapnia can be tolerated for many years with few symptoms, although early morning headache is relatively

common. Many patients tolerate arterial hypoxaemia well for many years before decompensation occurs. There is no universally accepted definition of acute-on-chronic respiratory failure in a patient with a background of COPD, although acidemia in the presence of a raised  $P_{aCO_2}$  with a raised bicarbonate indicates acute decompensation with a chronic respiratory acidosis. One of the problems resulting from the lack of standardized blood gas criteria to define acute-on-chronic respiratory failure is that the reported survival, both during the acute event and over the longer term, in different series of patients with respiratory failure varies widely, largely due to variation in the criteria used for inclusion of patients into the studies [35] (Fig. 24.3).

The most common definition of acute respiratory failure in such patients is a  $P_{aO_2}$  of less than 6.7 kPa (50 mmHg) with a  $P_{aCO_2}$  of greater than 6.7 kPa (50 mmHg) when breathing air, often associated with respiratory acidosis, in a patient whose symptoms have worsened compared with the stable clinical state [27,28]. The association of acidosis with more or increasing symptoms differentiates acute from chronic respiratory failure. There is also a huge variation in the ventilation rates and criteria for ventilation in patients with acute-on-chronic respiratory failure as a result of COPD, which makes it difficult to make comparisons of survival rates between studies. Using these blood gas criteria, mortality in the acute event in the UK, where ventilation rates are as low as 3%, is around 12% [27,28], which is as good as most series from throughout the world.

Once acute respiratory failure is suspected the diagnosis must be confirmed by arterial blood gas analysis. As

described above, the pH (hydrogen ion concentration) is helpful in assessing the degree of acute vs. chronic respiratory failure. The pH is compensated for by renal retention of bicarbonate, which usually takes several days to have its maximal effect.

The general principles of management are: (i) to correct life-threatening hypoxaemia; (ii) to correct life-threatening acidosis; (iii) to treat the underlying cause; and (iv) to prevent complications.

### Relief of hypoxia

The first priority in treatment of acute-on-chronic respiratory failure that occurs during exacerbations of COPD is the relief of hypoxia by the cautious administration of oxygen. Barach and Woodwell in 1921 [36] were the first to describe the adverse effects of the administration of high inspired concentrations of oxygen in two patients with 'shallow breathing'. In 1949, Donald [37] described decreased conscious levels in patients with respiratory failure who were given high concentrations of oxygen. Thereafter the use of controlled oxygen therapy was introduced with the development of safe and reliable modes of oxygen delivery with an  $F_{iO_2}$  of 30% or less [38,39].

Supplemental oxygen should be administered by nasal prongs at flows of 1–3 L/min or by a Venturi mask with the flow set to deliver 24–28% oxygen [40]. The Venturi mask produces the most predictable inspired oxygen concentrations. Concentrations from nasal prongs are less predictable, but the device is better tolerated by patients [41]. However, if nasal prongs are used, blood gases should be rechecked after 30 min [42]. On average, the

Fig. 24.3 Survival curves after an episode of acute-on-chronic respiratory failure in patients with chronic obstructive pulmonary disease. (After Martin *et al.* [132].)

$P_{aO_2}$  increases by 1.3 kPa (10 mmHg) as the  $F_{IO_2}$  is increased from 21 to 24% in patients with acute respiratory failure, and by 2.6 kPa (20 mmHg) when the  $F_{IO_2}$  is increased to 28% [40]. It is important to remember that an oxygen flow of 2 L/min by nasal prongs produces an  $F_{IO_2}$  of 25–35% [43]. Ideally, the goal of supplemental oxygen therapy should be to achieve a  $P_{aO_2}$  of greater than 8 kPa (60 mmHg). However, a  $P_{aO_2}$  of 6.6 kPa (50 mmHg) has been recommended as being adequate in acute-on-chronic respiratory failure [28]. Pulse oximeters have been used to measure the degree of oxygenation non-invasively, but provide no information on  $P_{aCO_2}$ . Moreover, the 95% confidence limits of pulse oximeters is 4% [44]. In most cases arterial blood gas measurements are required for accurate measurements of both  $P_{aO_2}$  and  $P_{aCO_2}$ .

Sedatives, especially opiates which further depress the ventilatory drive, should be avoided. In patients with a history of COPD aged greater than 50 years, oxygen at an  $F_{IO_2}$  of more than 28% via a Venturi mask or at 1–2 L/min via a nasal prongs should not be given until the arterial blood gases are known.

Respiratory stimulants such as doxapram (see Chapter 9) may be considered in patients with acidosis as a result of hypercapnia and hypoventilation in order to assist the patient for 24–36 h until the underlying factors precipitating the exacerbation improve, and so avoid the need for invasive mechanical ventilation [28,45]. The use of respiratory stimulants is somewhat controversial, particularly as studies have demonstrated that central respiratory drive is high in such patients [31,46,47]. An early study showed benefit, in terms of blood gases, from the use of doxapram compared with placebo [48]. Indeed, in this study, the number of patients requiring subsequent mechanical ventilation was similar in both the placebo and doxapram-treated groups. Jeffrey and colleagues [28] examined the effect of doxapram in a series of patients with COPD and hypercapnic respiratory failure. Again, there was a low incidence of mechanical ventilation and a mortality rate of only 12%, comparable with other studies in which mechanical ventilation was more frequently employed [35]. In this and an earlier study from the same group, the best predictor of death during an episode of acute respiratory failure was an arterial pH of less than 7.26 (hydrogen ion concentration  $>55$  nmol/L), which was associated with a higher mortality [27,28]. Based on these studies the authors suggested that oxygen should be administered to achieve a  $P_{aO_2}$  of more than 6.6 kPa (50 mmHg), while maintaining a hydrogen ion concentration of less than 55 nmol/L. If this could not be achieved the use of short-term doxapram was suggested [28]. Close monitoring of these patients is required to determine whether there is a response to such conservative treatment. If the patient's hydrogen ion concentration remains greater than 55 nmol/L, ventilatory support should be considered.

The decision to institute invasive ventilation should be made by a senior physician, who should consider the patient's premorbid state and any wishes of the patient and close relatives. The factors that encourage or discourage the use of invasive ventilation are discussed in Chapter 58 (see also Table 24.3).

### **Non-invasive ventilation in exacerbations of respiratory failure**

Recently, non-invasive positive pressure ventilation (NIPPV) via nasal masks has become available. Several early uncontrolled studies demonstrated the feasibility of NIPPV in patients with acute exacerbations of respiratory failure due to COPD [49–57]. These studies showed variable improvements in blood gas tensions. NIPPV has been shown in randomized controlled trials to be better than placebo [58,59]. The main advantage of NIPPV is the avoidance of tracheal intubation and hence the need for sedation. Furthermore, the technique can be applied in a high-dependency unit or a general ward, without the need for intensive care [60]. Thus this treatment can be applied to patients with severe COPD and respiratory failure who would be considered unsuitable for intubation.

The aims of NIPPV should be to improve gas exchange in order particularly to rectify acidosis, since pH or hydrogen ion concentration has been shown to be an important predictor of survival in patients with respiratory failure and COPD [28]. In addition the performance of the respiratory muscles is compromised in patients with severe COPD, since lung overinflation results in these muscles acting at a mechanical disadvantage [61]. In addition, the load on the muscles is increased as a result of increased airflow obstruction and the presence of intrinsic PEEP and because of the effects of hypercapnia and acidosis [62,63].

A number of studies have shown that NIPPV can improve hydrogen ion concentrations and reduce respiratory muscle work in respiratory failure [50,58,59,64]. However, there have been only three randomized controlled trials on the use of NIPPV in exacerbations of respiratory failure in patients with COPD [58,59,65]. In a study from the UK, Bott and colleagues [58] compared a control group of patients with an exacerbation of COPD and respiratory failure who received conventional treatment with a similar group who received NIPPV. Some patients in both treatment groups also received doxapram but in a non-standardized fashion. Small improvements in pH and breathlessness were demonstrated in the NIPPV group. Mortality was also less in the NIPPV group but only when patients who could not tolerate NIPPV were removed from the analysis. However, the pH in these patients when NIPPV was commenced was not at a level where many physicians would consider ventilation was indicated.

In another study of NIPPV, Kramer and colleagues [65] showed a significant fall in intubation rates for patients with respiratory failure, from 67% in those treated conventionally to 9% in those undergoing NIPPV. This study highlights the differences in the treatment of this condition in the USA, where all patients with respiratory failure who deteriorate on either conventional treatment or NIPPV are offered invasive ventilation, whereas in the UK relatively few patients who deteriorate despite treatment are offered intubation and ventilation [58]. However, the study from the USA showed that there was no difference in mortality between the NIPPV and the control group, although relatively few patients with COPD were included in this study [65].

A study by Brochard and coworkers [59] from several European centres again showed that the need for intubation could be reduced by the use of NIPPV. In this case, mortality was also significantly less in the NIPPV group (9%) compared with the conventionally treated group (29%). However, the differences in mortality disappeared after adjustments for intubation were made, suggesting that the benefit from NIPPV was due to a reduction in the need for intubation. In this study the mean pH was 7.28 and 7.27 in the standard treatment and NIPPV groups respectively, which is closer to the level where others have shown predicted survival [7,26–28].

These reports highlight two problems with all studies of patients with respiratory failure [35]: the first is the lack of standardization of the inclusion criteria, particularly the levels of blood gas abnormalities, and the inclusion of patients with respiratory failure due to different conditions; the second is the wide variation in intubation rates [66]. This makes comparisons between different studies difficult.

The selection criteria for treatment with NIPPV are therefore critical and more studies are required to determine at what stage in the exacerbation of respiratory failure NIPPV should be initiated. There is also a need to undertake a controlled trial of the respiratory stimulant doxapram as against NIPPV, particularly in the UK where this drug is still used, since in one study conventional treatment that included doxapram produced a mortality of only 12% in acute exacerbations of respiratory failure, which compares favourably with most other studies [35]. The selection criteria in most studies appears to be a pH of less than 7.35, a respiratory rate of greater than 30 breaths/min and a  $P_{aO_2}$  of less than 6 kPa (45 mmHg) [60]. Exclusion criteria are numerous, and include patients who require immediate intubation or who have had a recent cardiac arrest and those who have any specific cause of their decompensation, such as pulmonary embolism or septic shock. In a retrospective study, Ambrosino and colleagues [64] suggested a poor outcome from NIPPV was more likely in those patients who were underweight and had a reduced level of compliance with NIPPV, impaired

conscious levels and higher APACHE scores. In general these patients had a higher  $P_{aCO_2}$  and a lower pH, again suggesting the need to introduce NIPPV early to prevent deterioration.

Meacham Jones and colleagues [67] have compared the different modes of NIPPV in patients with exacerbations of COPD. They found that 1 h after the initiation of treatment the use of volume- or pressure-cycled ventilation and continuous positive airway pressure (CPAP) could all improve oxygenation, although CPAP had little effect on  $P_{aCO_2}$ . The addition of expiratory positive airway pressure was poorly tolerated and produced no additional benefit. It is useful therefore to have both volume- and pressure-cycled equipment available.

The use of NIPPV requires resources, both in terms of equipment and trained personnel. Further studies are required to determine the factors that predict the successful use of this treatment, and at least one recent study has cast some doubt on its previously uniformly successful outcome [68]. The controversy over the use of doxapram vs. NIPPV in patients with exacerbations of COPD and in respiratory failure remains. There has been no large controlled trial comparing these treatments. However, a recent report in a small group of patients, nine of whom received NIPPV and eight doxapram, with similar baseline  $P_{aO_2}$ , showed that both treatments improved  $P_{aO_2}$  although this improvement was not maintained with doxapram at 4 h [69]. NIPPV caused a fall in  $P_{aCO_2}$ , whereas those who received doxapram had no improvement in  $P_{aCO_2}$ . Interestingly, there was a significant improvement in pH with both treatments, although again the level of pH at the institution of treatment (7.3) was perhaps higher than in previous studies of doxapram.

### Mechanical ventilation

The priorities in the management of acute respiratory failure vary according to the aetiology. However, the primary aims of treatment are the same in all cases: to maintain patent airways, ensure adequate alveolar ventilation and oxygenation while treating, if possible, the primary condition.

### Indications

The most common indication for mechanical ventilation is during and following major surgery [70]. In most non-surgical patients being considered for mechanical ventilation the indications are clear-cut in that adequate respiratory effort cannot be maintained using other supportive means and alveolar hypoventilation occurs, as shown by a high or rising  $P_{aCO_2}$  and a falling pH. Thus without such ventilatory support the patient may die. Patients with non-hypercapnic respiratory failure can be

maintained initially by increasing the concentration of inspired oxygen via a conventional or full-face mask with CPAP. Modest gains in oxygenation must be balanced against the risks of intubation and positive pressure ventilation [71].

The assessment is clearer in patients with hypercapnic respiratory failure, since if conventional treatment and non-invasive ventilation have failed then without mechanical ventilation the patient will die. In conventional clinical practice, a  $P_{aO_2}$  of less than 8 kPa (60 mmHg), despite an  $F_{IO_2}$  of greater than 0.6, and hypercapnia are the common indications for ventilation. Patients with COPD can obviously have high stable levels of  $P_{aCO_2}$  without evidence of respiratory distress. Other factors that favour the institution of mechanical ventilation are a rapid increase in hypercapnia, producing uncompensated respiratory acidosis, mental confusion due to either severe hypercapnia or hypoxaemia, tachypnoea (>35 breaths/min) and a clinical judgement of impending exhaustion in the patient.

It is critical when considering mechanical ventilation to assess the patient's condition prior to the onset of respiratory failure and ensure that mechanical ventilation is justifiable. It may be inappropriate, even over the short term, to ventilate patients who have advanced malignant disease, progressive neurological disorders or chronic respiratory diseases with poor quality of life. The British Thoracic Society guidelines for the management of COPD list the factors that influence the institution of mechanical ventilation in these patients [72] (Table 24.3).

### *Airway access*

Mechanical ventilation initially requires access to the airway, usually obtained by an endotracheal or nasotracheal tube. The latter has the advantage that it is easier to secure once *in situ* and tends to be more comfortable for the patient and hence less sedation is often required. However, nasal tubes are narrower and longer and therefore have a greater resistance and are more likely to

become obstructed by secretions. Laryngeal and tracheal trauma can occur from endotracheal tubes, although this is less of a problem than previously thought [73]. Improvements in endotracheal tube design, together with advances in airway management, have reduced the number of patients requiring tracheostomy. However, this is necessary in patients who require long periods of ventilation, or for the relief of upper airway obstruction or the management of copious secretions in patients who have an inadequate cough. Endotracheal tubes can be tolerated for at least 3 days in most patients and often somewhat longer [74]. In addition, tracheostomy is sometimes required in patients who are difficult to wean from ventilators. However, tracheostomy is associated with several complications, for example haemorrhage, infection, erosion of the tube into the oesophagus, tracheal stenosis, tube blockage and respiratory infection.

### *Modes of ventilation*

#### *Intermittent positive pressure ventilation (IPPV)*

This is the usual form of ventilation in the operating room. The patient is anaesthetized and paralysed and therefore makes no spontaneous respiratory effort; a simple ventilator intermittently inflates the lung at a tidal volume and respiratory rate sufficient to maintain appropriate gas exchange. A similar form of ventilation is used in patients in the intensive therapy unit (ITU) who are paralysed with muscle relaxants or who are unable to make any inspiratory efforts.

#### *Intermittent mandatory ventilation*

In this form, the patient receives ventilation at a predetermined rate and volume from the ventilator but can also breathe spontaneously through the ventilator circuit [71]. Interactive ventilators have been developed that can sense the patient's breathing and avoid coincidental, spontaneous and ventilator-assisted breathing, which can result

**Table 24.3** Factors that influence the institution of mechanical ventilation in patients with COPD.

#### *Factors to encourage use of IPPV*

A demonstrable remedial reason for current decline, e.g. radiographic evidence of pneumonia or drug overdosage  
The first episode of respiratory failure  
An acceptable quality of life or habitual level of activity

#### *Factors likely to discourage use of IPPV*

Previously documented severe COPD that has been fully assessed and found to be unresponsive to relevant therapy  
A poor quality of life, e.g. being housebound, in spite of maximal appropriate therapy  
Severe comorbidities, e.g. pulmonary oedema or neoplasia

NB: Neither age alone nor the  $P_{aCO_2}$  are a good guide to the outcome of assisted ventilation in hypercapnic respiratory failure due to COPD. A pH of >7.26 is a better predictor of survival during the acute episode.

IPPV, intermittent positive pressure ventilation.

in high airway pressures and is uncomfortable for the patient.

#### *Synchronized intermittent mandatory ventilation (SIMV)*

In this form of ventilation, the ventilator senses the ventilatory pressure generated by the patient and does not always deliver a mechanical breath, although the patient breathes through the ventilatory circuit. However, sufficient mandatory breaths synchronized to the patient's inspiratory efforts are delivered to the patient and it is therefore critical that the ventilator has a sensitive trigger mechanism. Thus SIMV allows adequate ventilation while enabling patients to take spontaneous breaths.

#### *Mandatory minute ventilation*

This technique enables a preset minute volume to be achieved which, if exceeded by the patient, results in no additional ventilation being provided. Thus the ventilator provides the shortfall in minute ventilation either by inspiratory pressure support or SIMV.

#### *Inspiratory pressure support (IPS)*

This form of ventilation is useful in patients who are spontaneously breathing but whose efforts are insufficient to achieve an adequate tidal volume [75]. Thus each inspiration is assisted by raising the airway pressure to a preset value. The respiratory rate is determined by the patient.

#### *Proportional assisted ventilation*

In this form of ventilation, the ventilator senses the inspiratory flow achieved by the patient and delivers pressure support proportional to the ventilatory effort made by the patient [76,77]. Thus if the patient increases the inspiratory 'effort' so does the ventilator. Although this form of ventilation is highly interactive and often very comfortable for the patient, it does require an alert patient who can initiate appropriate respiratory efforts.

#### *High-frequency ventilation*

This is achieved by injecting volumes of gas at high frequencies, up to 300/min [78]. Thus tidal volume is small, and indeed is less than the dead space and thus does not improve gas exchange by conventional means. The advantage of this form of ventilation, which can be used in spontaneously breathing patients, is to reduce peak airway pressures. It is most commonly used in ARDS when pulmonary compliance is low. It has also been used in patients with cardiac failure or bronchopleural fistula.

#### *Positive end-expiratory pressure*

This technique applies positive pressure at the end of expiration and thus lung volumes, particularly functional residual capacity (FRC), are increased [78]. The aim of this treatment is to prevent small airway closure and thus improve ventilation, reducing intrapulmonary hypoxaemia and hence pulmonary shunt. The disadvantage is a reduction in venous return and cardiac output, which can counteract the improvement in arterial oxygen tensions by an overall reduction in tissue oxygen delivery [79].

#### *Ventilator management*

In the case of routine surgical patients requiring mechanical ventilation on the ITU, analgesia and sedation is usually given with opiates and/or benzodiazepines and muscular paralysis is not usually necessary. It is important that all the staff in the ITU are completely familiar with the ventilator being used; this is more important than the particular type used. Patients can be ventilated by volume- or pressure-cycled machines. Volume-cycled machines deliver a fixed predetermined tidal volume and generate whatever pressure is required, breath by breath, to achieve that volume. In contrast, pressure-cycled machines deliver a predetermined pressure, and tidal volume therefore depends on the overall impedance to inflation and varies over time. Volume-cycled machines are often preferred since they continue to deliver a preset tidal volume irrespective of changes in the patient's airway resistance. However, when using nasal ventilation, large tidal volumes are required for adequate ventilation (approximately twice those of intubated patients) in order to compensate for upper airway dead space and the inevitable leaks around the mask, and volume-cycled machines may therefore be less suitable for this type of ventilation. Nomograms exist for the calculation of expected volumes, although it is always advisable to check the arterial blood gas tensions after instituting IPPV.

The tidal volume is usually set at approximately 10 mL/kg body weight and respiratory rate at 10–20 breaths/min and therefore minute ventilation is 100–150 mL/kg. In patients with COPD the tidal volume is often set at a lower level (7–9 mL/kg) in order to avoid the development of auto-PEEP (see p. 706).

#### *Ventilating patients with airway diseases*

There are many problems with ventilating patients who have severe airways obstruction [80,81]. Patients with severe asthma and COPD are hyperinflated and require high peak pressures during mechanical ventilation and hence the risk of pneumothorax and pneumomediastinum is increased [82]. It should be remembered that it is not necessary to correct the  $Paco_2$  rapidly in patients

with severe hypercapnia due to COPD. To keep inflation pressures down, a small tidal volume is used. To minimize gas trapping, a prolonged expiratory time is required with an inspiratory–expiratory ratio of 1:4 or 1:5. Peak inflation pressures are usually best kept below 30–35 cmH<sub>2</sub>O (2.94–3.43 kPa). Thus to avoid overinflation and high airway pressures and thus prevent barotrauma it may be necessary to accept a degree of hypercapnia [83].

Most patients require 35% inspired oxygen. Regular blood gas analysis allows the inspired oxygen concentration and the level of PEEP to be adjusted against the  $P_{aO_2}$  and the minute ventilation against the  $P_{aCO_2}$ .

#### *Auto-PEEP (intrinsic PEEP)*

Auto-PEEP, or intrinsic PEEP, occurs because patients with COPD and acute respiratory failure have severe airways obstruction and decreased pulmonary elastic recoil. Maximum expiratory flow is markedly reduced and there is a prolonged expiratory time, greater than required to permit a complete exhalation of inspired gas. In addition, the patients are commonly tachypnoeic and these factors produce a shortened expiratory time, so that inspiration starts before expiration has been completed, resulting in dynamic air trapping and an alveolar pressure that remains positive at the end of expiration. The resulting increase in lung volume forces the patient to breathe at the upper, less compliant portion of the pressure–volume curve, which increases the elastic load to breathing. This overinflation results in the respiratory muscles operating in an unfavourable position on their length–tension curve. Such auto-PEEP can have significant circulatory effects [84], since positive alveolar pressure can impede venous return and hence impair circulatory function. Dynamic overinflation and auto-PEEP may also increase the development of barotrauma during mechanical ventilation. Auto-PEEP can be measured during mechanical ventilation by the end-expiratory port occlusion method, where the expiratory port is occluded near the time when the next inspiration is anticipated. Because the expiratory flow is blocked, pressure in the ventilatory tube equilibrates with alveolar pressure, allowing the level of PEEP to be measured on the ventilator manometer [85]. The occlusion method is difficult to apply in patients who are making spontaneous inspiratory efforts, and under these circumstances auto-PEEP can be measured by inserting an oesophageal balloon and recording oesophageal pressure and inspiratory flow [86]. The majority of patients with an exacerbation of COPD severe enough to cause respiratory failure develop auto-PEEP, and the levels may be high (>10 cmH<sub>2</sub>O [>1 kPa]) [80,87].

#### *Inspiratory muscle fatigue*

In exacerbations of COPD the increased work of breathing

is borne largely by the inspiratory muscles [88]. The additional problem of dynamic overinflation, which puts the inspiratory muscles at a considerable disadvantage, and metabolic factors such as hypocalcaemia, hypophosphataemia, hypomagnesaemia, malnutrition and respiratory acidosis all decrease respiratory muscle strength and may lead to inspiratory muscle fatigue [63,89–92]. There is debate over the optimal mode of ventilation in patients with COPD and respiratory failure, largely resulting from controversy about the importance of inspiratory muscle fatigue in these patients.

#### *Ventilating patients with alveolar diseases*

Patients with reduced pulmonary compliance also have specific problems related to mechanical ventilation [83,93–95]. These patients are commonly those with ARDS, and in this case adequate mechanical ventilation necessitates high inflation pressures, a high  $F_{IO_2}$  and PEEP. This therefore increases the risk of barotrauma and pneumothorax. These side-effects can only be limited if airway pressures are kept as low as possible, necessitating small tidal volumes and the acceptance of a degree of hypercapnia [83]. Certain patients may benefit from use of high-frequency ventilation, thus allowing adequate gas exchange at lower peak airway pressures. PEEP is extremely useful in these patients, both by opening closed small airways, thereby improving oxygenation, and by lifting the lung on to a more compliant part of the pressure–volume curve.

#### *General management of ventilated patients*

Managing patients undergoing IPPV requires continuous skilled nursing support and immediate access to staff competent to deal with ventilator and intubation problems. Frequent or continuous monitoring of the ECG, heart rate, oxygenation, arterial blood gases and arterial blood pressure, urine output and ventilator parameters is required on a standard chart. The  $P_{aCO_2}$  should not be lowered precipitously, particularly in patients where the resting level is known to be high. It is better to aim for a normalization of pH rather than for a specific  $P_{aCO_2}$ .

Sedatives and analgesics are commonly administered by constant infusion in the form of opiates [96]. This may result in problems associated with respiratory distress, depression, vasodilatation, reduced gastric motility and tolerance. The duration of action of benzodiazepines can be a problem. Midazolam can be useful in this regard, since it has a relatively short half-life of several hours and can be given by continuous infusion [97]. Regular clearance of airway secretions by suction is often necessary. Continuous monitoring of oxygenation by oximetry and regular blood gas measurements are essential, particularly in the early stages of treatment.

Since many factors influence oxygen delivery to, and uptake by, the tissues, monitoring of cardiac function is often crucial. Depending on the circumstances, systemic arterial, pulmonary arterial and pulmonary wedge pressures, cardiac output, pulmonary and systemic vascular resistance, and mixed venous oxygen tensions and saturations may be required. Venous oxygen tension is a particularly useful index of the balance between oxygen supply to, and extraction by, the tissues [98]. Oxygenation should also be judged in the light of the patient's usual  $P_{aO_2}$  rather than by normal values. The  $F_{iO_2}$  can be increased, although high concentrations of oxygen, particularly for a long periods, can lead to oxygen toxicity. Clearly it would be unwise to run the risk of the patient dying of hypoxia for fear of pulmonary oxygen toxicity if a higher  $F_{iO_2}$  is needed, and some compromise has to be found in each case. As a rough guide, if an  $F_{iO_2}$  of 0.7 does not produce acceptable values for  $P_{aO_2}$ , then it may be better to apply PEEP rather than increase the  $F_{iO_2}$ . PEEP will result in a further increase in mean thoracic pressure and hence a greater decrease in venous return. Clearly this disadvantage has to be set against the benefit of improved oxygenation. In practice it may be necessary to measure mixed venous  $P_{O_2}$  and cardiac output in order to compute the best level of PEEP in an individual patient given these conflicting effects. If PEEP is ineffective or inadequate, then of course the  $F_{iO_2}$  has to be increased. In clinical practice it is not uncommon to have to use a high  $F_{iO_2}$  and then apply PEEP in the hope of being able to reduce the  $F_{iO_2}$ .

#### Nutrition

Adequate nutrition is crucial in ventilated patients [99]. This is particularly true in those with sepsis, who have a very high oxygen consumption, or in those who require prolonged ventilation. Muscle wasting affects all muscles including those of respiration and leads to difficulties in weaning [100]. Electrolyte and calcium disturbances, hypophosphataemia and hypomagnesaemia can also cause muscle weakness [101]. The  $CO_2$  load can be reduced in patients with hypercapnia by providing less of the calorie requirements as carbohydrate and more as fat. However, there have been no randomized controlled studies examining the role of nutrition in patients with COPD [102]. In addition complications as a result of either enteral nutrition or total parenteral nutrition are frequent. In addition, malnutrition, which may coexist in patients with COPD [103], may be exacerbated by mechanical ventilation [104]. There is some evidence from retrospective uncontrolled studies of patients requiring long-term (>3 days) mechanical ventilation that nutritional supplementation improved the weaning rate in these patients [105]. It would therefore seem reasonable to provide nutritional support for patients who are malnourished at presenta-

tion or who require prolonged ventilation. The enteral route is the preferred mode of administration.

#### Physiotherapy

Most patients, particularly those with airway diseases, have an increase in airway secretions during mechanical ventilation and have impaired cough effectiveness. Thus it would seem reasonable to employ chest physical therapy to assist removal of secretions. However, several studies have been unable to show any improvement in pulmonary function or objective evidence of improved removal of secretions when physiotherapy is employed in patients with exacerbations of COPD [106,107]; there is certainly no benefit in patients with scant sputum production [108,109]. Physical therapy can also worsen  $P_{aO_2}$  and should only be considered in patients with large amounts of sputum production [108]. It is therefore a relative contraindication in most patients with COPD and respiratory failure.

#### Weaning from mechanical ventilation

In most patients with respiratory failure, weaning can be achieved without much problem by the withdrawal of sedation and muscle relaxants, allowing the patient to breathe spontaneously prior to extubation. In a minority of patients weaning is difficult and this is particularly true of those with COPD. Successful weaning relates to several factors, including achievement of adequate oxygenation with an  $F_{iO_2}$  of less than 0.4, recovery of the underlying condition that precipitated mechanical ventilation, attainment of stable cardiovascular function and the resolution of infection [110] (Table 24.4). The most important factors determining the success or failure of weaning are the load imposed on the respiratory system, respiratory drive and the capacity of the muscle pump [110]. Every effort should be made to reduce the load imposed on the respiratory system before weaning is attempted, for example by treatment of bronchoconstriction and pulmonary oedema. CPAP is useful in patients in whom a reduction in FRC causes hypoxaemia and reduced pulmonary compliance. In addition, CPAP is useful in patients with airway obstruction who develop intrinsic PEEP. Thus in many

**Table 24.4** Measurements associated with failure of weaning from mechanical ventilation.

---

Tidal volume, breathing spontaneously, <5 mL/kg
Vital capacity, <10 mL/kg
Alveolar-arterial oxygen tension difference, >40 kPa (300 mmHg)
Dead space/tidal volume, >0.6
Minute ventilation (MV), >10 mL/kg
Maximum voluntary ventilation, <2×MV
Maximum inspiratory pressure, >-20 cmH <sub>2</sub> O

---

patients CPAP reduces the ventilatory work during weaning [111]. The disadvantage of CPAP is that it may increase the load on the muscles of expiration and may aggravate overventilation and thus hypercapnia.

Patients require a high respiratory drive and need to be cooperative during weaning. Thus sedative drugs must be withdrawn before weaning, bearing in mind the long half-life of some of these agents such as benzodiazepines. In order to optimize the effectiveness of the respiratory muscle pump, adequate nutrition, control of sepsis and reversal of acidosis are particularly important. A good deal of support and encouragement is required from the ITU team during weaning. It is unlikely that a trial of weaning will be successful on the first attempt and it is important that patients are not deprived of sleep by repeated attempts. There is no definitive strategy for successful weaning. There have also been no controlled trials indicating that one technique is more successful than another. The usual technique is to gradually reduce the number of machine breaths with SIMV, allowing the patient to breathe spontaneously. Alternatively, the mechanical ventilation should be stopped and the patient allowed to breathe spontaneously with the withdrawal of ventilatory support for progressively longer periods of time.

IPS is increasingly used to aid weaning. This can be gradually reduced and the work progressively transferred from the ventilator to the patient. Proportional assist ventilation is a relatively recent technique that uses the mechanical ventilator to deliver pressure support in proportion to the patient's own inspiratory efforts, thus allowing patients to receive the correct degree of support which they perceive to be necessary on a breath-by-breath basis [74].

Non-invasive ventilation has also been used to facilitate weaning, although there are no controlled trials. However, uncontrolled studies suggest the benefit of NIPPV in chronically ventilator-dependent patients [112]. Before initiating NIPPV, patients should be capable of approximately 15 min of independent ventilation. Usually NIPPV is required for the first 48 h and thereafter for progressively shorter periods.

Weaning from mechanical ventilation is particularly difficult in patients with COPD [113]; again there are no published studies indicating the best technique to wean such patients. Traditionally the maximum inspiratory pressure ( $P_{I\max}$ ) has been used as a measure of respiratory muscle strength and as a reflection of the patient's ventilatory requirements. Previously it was thought that patients should be capable of generating a  $P_{I\max}$  more negative than  $-30\text{ cmH}_2\text{O}$  ( $2.94\text{ kPa}$ ) and have a minute ventilation of less than  $10\text{ L/min}$  to be successfully weaned [114], although this has subsequently been shown to have a high false-positive rate [115]. In a recent prospective study of weaning, the breathing frequency to tidal volume ratio, an

index of rapid shallow breathing, was found to be the most accurate predictor of weaning outcome [115]. A breathing frequency to tidal volume ratio of greater than  $100\text{ breaths/min/L}$  was associated with a 95% failure in a weaning trial. However, it should be emphasized that there is still much debate in this field [116].

## Complications

### Barotrauma

During mechanical ventilation in general ITU patients the incidence of pulmonary barotrauma is relatively low, occurring in 1–8% of patients [117,118]. The frequency increases significantly in patients with ARDS [117]. Factors associated with an increased incidence of barotrauma are high peak airway pressures, high levels of both external and intrinsic PEEP and high tidal volumes [117,119–122]. The ventilatory settings should be adjusted to try to maintain peak airway pressure below  $40\text{ cmH}_2\text{O}$  ( $3.92\text{ kPa}$ ).

### Gastrointestinal bleeding

Gastric erosions or ulceration producing gastrointestinal bleeding occur in patients with respiratory failure, with an incidence of around 20% in general ITU patients [123]. The incidence appears to be lower, around 9%, in patients with COPD. The risk of gastrointestinal bleeding is greatly reduced by continuous enteral feeding and maintenance of gastric pH above 4 may reduce the incidence [124]. However, the risk of raising intragastric pH is an increased growth of Gram-negative bacteria in the stomach and so an increased risk of nosocomial pneumonia [125,126]. However, it has been suggested that patients with COPD and acute respiratory failure may not benefit from ulcer prophylaxis, particularly if they are being fed enterally [127].

### Nosocomial pneumonia

Nosocomial pneumonia (see Chapter 13) in the ITU is usually caused by Gram-negative bacilli, which may be resistant to common antibiotics [128]. The most common source of organisms appears to be aspiration of microorganisms that colonize the pharynx [129], and this may occur within 72 h of admission to the ITU [130]. Other complications include cardiac dysrhythmias and pulmonary emboli. Psychological disturbances are also common among ITU patients.

## Prognosis

A detailed review of the prognosis in ventilated patients in ITU is beyond the scope of this chapter. Specifically in

patients with COPD, the short-term mortality in acute respiratory failure was established in a number of studies in the 1960s and 1970s and has been reviewed by Hudson [131]. In these early studies the mortality ranged between 22 and 34% during the acute episode. More recent studies have reported a mortality for an acute episode of respiratory failure of between 6 and 16% [27,28,44,45,132,133]. Differences in patient selection may well be the most important factor accounting for the variation in mortality between different studies. Indeed the study that showed the best prognosis included patients with the least severe disease [133].

Several studies have shown that the best predictor of mortality in patients with acute-on-chronic respiratory failure is the degree of acidaemia. Thus a pH of less than 7.26 (hydrogen ion concentration  $>55$  nmol/L) is associated with an increased mortality [27,28]. The  $Paco_2$  is much less predictive, because most of these patients have chronic hypercapnia and the severity of the acute phase is better reflected by the degree of acidosis rather than the absolute level of  $Paco_2$ . The initial level of  $Pao_2$  on admission was a determinant of mortality in some studies [40] but not in others [27,28]. It is interesting to note that mechanical ventilation during the acute episode is not itself associated with an increased mortality, although there are no studies that have specifically addressed this issue.

The long-term mortality of patients with COPD who survive an episode of acute respiratory failure is in general very poor; 50% of these patients are dead at 3 years [132–136].

## Specific types of respiratory failure

The causes of respiratory failure are identified in Tables 24.1 and 24.2 and are covered fully in the chapters indicated in these tables. Those that require further elaboration are considered here.

### Drugs

#### CNS depressants

Opiates, sedatives and tranquillizers may cause alveolar hypoventilation if taken as an overdose or if given in excessive therapeutic dosage. Intubation with mechanical ventilation may be required if respiratory depression is severe. All drugs that depress the nervous system should be used with caution in patients with pulmonary disease, particularly those with COPD who have chronic hypercapnic respiratory failure. Opiate antagonists, such as naloxone, are of value in opiate overdose and flumazenil is useful in benzodiazepine overdose. Rarely methadone or heroin overdosage can result in the complication of pulmonary oedema [137,138].

### Postoperative apnoea

Postoperative apnoea may be due to excessive premedication with opiates. It can also occur after the use of suxamethonium, particularly in patients with a hereditary deficiency of pseudocholinesterase. In these cases mechanical ventilation should be continued until the effects of the suxamethonium wears off.

### Poisoning

Organophosphorus compounds are used in insecticide sprays and may be absorbed through the skin (even through clothing) or mucous membranes. Poisoning results in tremors, twitching, convulsions, contracted pupils, salivation and bradycardia. Treatment is by repeated intravenous injection of atropine (2–3 mg immediately and 1–2 mg every hour). Sputum removal is accelerated by intravenous pralidoxime 1 g every hour. Nevertheless, mechanical ventilation may be required.

### Laryngeal oedema

Laryngeal oedema may result from inhalation of irritant vapours, clumsy attempts at intratracheal intubation or angioneurotic oedema. In the latter, other allergic manifestations such as wheeze, urticaria and sneezing may be present. Stridor is usual. Angioneurotic oedema should be treated immediately with 0.5 mL epinephrine (adrenaline) 1 in 1000 solution intramuscularly and intravenous injection of 200 mg hydrocortisone and 20 mg chlorpheniramine. Needle tracheotomy, using a large Medicut cannula inserted through the cricothyroid membrane, may be necessary as a stopgap measure if formal tracheotomy is required.

### Neurological disorders

Neurological disorders can result in respiratory morbidity and mortality due to depression of ventilation (whether caused centrally or via respiratory muscle weakness) or pulmonary oedema. This occurs in various acute cerebral insults and in recurrent aspiration from the upper airway as a result of a primary muscle disease or diseases affecting the brainstem. Abnormal breathing patterns can affect various levels of the CNS associated with the pathways of respiratory control. Respiratory depression can occur in various conditions associated with acute cerebral dysfunction, including encephalitis, stroke and tumours, which cause cerebral oedema and raised intracranial pressure.

### Pulmonary oedema

The so-called neurogenic pulmonary oedema syndrome is

associated with acute brain injury, especially following trauma, subarachnoid haemorrhage and severe convulsions. It is often associated with raised intracranial pressure and cerebral oedema. The mechanism is probably associated with a sudden rise in systemic and pulmonary vascular pressures as a result of a massive adrenergic discharge mediated by the hypothalamus [139,140]. An additional factor may be loss of integrity of the pulmonary capillaries, producing the high protein content in the oedema fluid. Oxygen is usually required, although if the  $P_{aCO_2}$  is raised positive pressure ventilation may be needed.

### Respiratory muscle dysfunction

The respiratory muscles include the diaphragm, intercostal muscles, scalene muscles and abdominal muscles. The pattern of dysfunction depends on which muscles are affected. In general there are three common patterns:

- 1 generalized weakness, as in the diffuse neuropathies and myopathies;
- 2 conditions where the diaphragm is spared but other respiratory muscles are involved, such as lower cervical quadriplegia;
- 3 unilateral and bilateral diaphragm weakness or paralysis resulting from disorders of the phrenic nerves, or muscle disorders that mainly affect the diaphragm. These are dealt with in greater detail in Chapter 45.

### Clinical assessment

A patient who presents with breathlessness, without pulmonary or cardiovascular disease, suggests the possibility of global muscle weakness. There may also be a history of ineffective cough or unexplained respiratory infections. A family history of diffuse neuropathy or myopathy is important. Clinical signs may not be obvious, although there may be generalized wasting of the peripheral muscles. Patients with severe diaphragmatic weakness show paradoxical inward abdominal motion during inspiration when breathing at rest, particularly in the supine position when the diaphragm is unable to counteract the weight of the abdominal contents.

### Investigations

Hemidiaphragm paralysis can usually be identified from a plain chest radiograph, although fluoroscopic screening during sniffing is sometimes required to produce the paradoxical upward movement of the paralysed diaphragm [141]. Bilateral diaphragm paralysis is difficult to assess on plain chest radiography or fluoroscopy.

A reduction in vital capacity (VC) is usual but is relatively non-specific. Therefore the combination of small VC and small clear lung fields on the chest radiograph is sug-

gestive of respiratory muscle weakness. Sequential measurements of VC may be a useful index of failing respiratory muscle function. Severe diaphragmatic weakness is associated with smaller VC when supine than when erect as a result of the abdominal contents affecting the diaphragm in the supine position. Normally VC falls by only 5–10% when moving from the erect to the supine position and even in patients with lung disease the fall is no more than 30% [142]. Patients with severe diaphragmatic weakness have a fall in VC of more than 30% [143].

In patients with respiratory muscle weakness, daytime hypercapnia does not occur until muscle strength is less than 30% of normal, unless there is coexisting pulmonary or airways disease or reduced respiratory drive [144]. Gradual development of global muscle weakness may result in hypoventilation, which occurs initially only at night during REM sleep [145]. This can be detected by continuous monitoring of oxygenation and  $CO_2$  tensions during sleep.

Respiratory muscle strength can be measured by assessing maximum static inspiratory ( $P_{I\max}$ ) and expiratory ( $P_{E\max}$ ) pressures at the mouth [146,147]. A  $P_{I\max}$  more negative than  $-80\text{ cmH}_2\text{O}$  (7.85 kPa) excludes clinically significant respiratory muscle weakness. Equivocal values can be difficult to interpret and may require further investigation.

### Myasthenia gravis

Myasthenia gravis is an uncommon autoimmune disease of neuromuscular junctions that leads to a reduction in the number and effectiveness of acetylcholine receptors and thus to impaired neuromuscular transmission, resulting in weakness and undue fatigue [148–152]. The characteristic fatigability occurs following repetitive action or prolonged contraction and recovers with rest. Extraocular, bulbar, neck, limb girdle, distal limb and trunk muscles are involved in that order. Patients with myasthenia gravis occasionally develop respiratory failure [153]. Anticholinesterase drugs (e.g. edrophonium), which increase the concentration of acetylcholine at the neuromuscular junction, are used in the initial diagnosis and treatment. The diagnosis may be confirmed by measurement of acetylcholine antibodies and electromyography. Intravenous edrophonium chloride is used in a diagnostic test and increases muscle strength within minutes in a patient with the disease. Longer-acting oral anticholinesterases, such as neostigmine or pyridostigmine, are used to maintain strength throughout the day. However, an overdose of anticholinesterase medication may result in a 'cholinergic crisis' with severe muscle weakness that may be difficult to differentiate from weakness due to worsening myasthenia, a 'myasthenic crisis'. Separation of the two types of crisis can be made by giving 10 mg edrophonium, which

increases strength in a myasthenic crisis but decreases it in a cholinergic crisis. It is wise to prepare for ventilatory support before administering edrophonium since hypoventilation, with a marked increase in retention of bronchial secretions, may occur in patients with a cholinergic crisis. Corticosteroids and immunosuppressive therapy are now becoming the initial treatment of choice for myasthenia, although a transient exacerbation may be seen in the early days of therapy. Ventilator support may be necessary until strength returns with appropriate readjustment of medication. Repeated measurements of inspiratory muscle pressure or VC are of value in monitoring the progress of the disease and in adjusting drug dosage. In many patients thymectomy produces a substantial improvement whether or not a thymoma is present.

### Polyneuropathy

Infective polyneuropathy (Guillain-Barré syndrome) is a progressive central demyelinating neuropathy of unknown aetiology. It is characterized by the fairly rapid development of flaccid paralysis of muscles following a viral infection. Progressive muscle weakness may occur over days or weeks. Weakness usually begins in the feet and ascends but may also begin cranially. The muscles of respiration may be affected leading to respiratory failure, which can develop fairly rapidly over 24–48 h. Monitoring of respiratory muscle function is vital. Twice-daily measurements of VC are usually recommended while the disease is progressing [154]. Monitoring of arterial blood gases is also recommended and artificial ventilation may be necessary in 20–50% of affected individuals [154,155]. Mechanical ventilation is necessary when the VC falls to between one-third and one-half of the predicted normal values. In practice the decision is more often made on clinical grounds because of a deteriorating respiratory effort, ineffective cough or inability to swallow [156]. Ventilatory support may be required for many weeks, necessitating tracheostomy, although most patients eventually make a good recovery. However, the potential for ventilator-associated complications including infections and pulmonary embolism is high. Suxamethonium should not be used since it may cause dangerous hyperkalaemia [157]. Autonomic dysfunction may complicate the management, with alternating bouts of tachycardia and bradycardia and fluctuations in blood pressure. Corticosteroid therapy is not now considered to be of value in the treatment of this condition, the management of which is largely supportive, although intravenous gammaglobulin or plasma pheresis may be helpful in some cases.

### Poliomyelitis

The high prevalence of poliomyelitis during the 1950s and

the requirement for ventilatory support with the iron lung has now receded in developed countries as a result of widespread immunization. Nevertheless, polio is still a common disease worldwide. Respiratory failure may be due to bulbar or spinal poliomyelitis or a combination of the two.

In spinal polio, the development of respiratory failure may be detected clinically as a feeble cough. However, serial measurements of VC and arterial blood gas tensions should complement clinical observations. Mechanical ventilation should be introduced when the VC falls to one-quarter of the patient's predicted value [158]. A mechanical ventilator can be used, thus avoiding tracheostomy. Should bulbar paralysis also develop, then tracheostomy is required with substitution of IPPV. In bulbar polio, laryngeal paralysis results in an ineffective cough and aspiration of secretions. Patients should be nursed in a 10° head-down position with regular aspiration of pharyngeal secretions. Feeding should be through a nasogastric tube. Tracheostomy may be required using a cuffed tube to prevent aspiration of secretions. It has been increasingly appreciated in recent years that late respiratory complications occur in poliomyelitis, up to 30 years after the original illness [159]. Muscles that were affected acutely are impaired as a result of late degeneration and the loss of motoneurons. The result is gradually increasing respiratory muscle weakness leading to respiratory failure. Ventilation in this case may be particularly troublesome at night, with resultant symptoms of daytime sleepiness and headache [160]. This so-called 'post-polio' syndrome tends to occur in those who developed respiratory muscle weakness during the original illness or in those who develop marked scoliosis [161]. Treatment with NIPPV may be necessary over the long term.

### Tetanus

Tetanus is a common cause of mortality in underdeveloped countries but in the developed world is now uncommon as a consequence of the widespread use of prophylaxis [162,163]. The condition results from infection of penetrating wounds with *Clostridium tetani*, which secretes an endotoxin taken up by nerve endings and transmitted to the CNS. The toxin interferes with the release of acetylcholine at the motor endplates and with the release of inhibitory neurotransmitters in the spinal cord. Muscle tone is markedly increased and the muscle is hyperexcitable, with resulting trismus and severe spasms in response to slight stimuli. Similar disinhibition of the autonomic nervous system may lead to labile hypertension, tachycardia, pyrexia and profuse sweating [164]. In the absence of intensive care facilities, death is usually due to asphyxia during respiratory muscle spasms. Control of the spasms with muscle paralysis using curare and IPPV reduces the respiratory death rate, although death may

still occur during autonomic storms due to myocarditis or brainstem lesions. Modern management in an ITU has reduced mortality to 11% [165].

Treatment consists of wound débridement, penicillin, passive immunization with immunoglobulin and active immunization. Spasms may be treated with high doses of diazepam or chlorpromazine [166]; if spasms are severe, curare and IPPV via a tracheostomy should be commenced. The autonomic cardiovascular changes can usually be controlled by intravenous beta-blockers or by morphine [167]. Enteral or parenteral nutrition is required.

### **Cervical cordotomy**

Bilateral high cervical cordotomy for intractable pain may result in alveolar hypoventilation, thought to be due to section of respiratory reticulospinal tracts. If the corticospinal pathways are left intact, the behavioural system may maintain ventilation when the patient is awake while hypoventilation and apnoea occur during sleep. Treatment is the same as for primary alveolar hypoventilation.

### **Myxoedema**

Occasional patients with myxoedema develop type II respiratory failure that responds to treatment with thyroxine. Ventilatory responses to hypercapnia and hypoxia are often reduced in these patients [168].

### **Inhaled foreign body**

An inhaled foreign body or food, most often a chunk of meat, can impact in the larynx and result in acute total airway obstruction, with choking, cyanosis and collapse. Prompt application of Heimlich's manoeuvre may be life-saving [169].

### **Respiratory failure in children: respiratory distress syndrome (hyaline membrane disease)**

Respiratory distress syndrome (RDS) in the newborn, or hyaline membrane disease, is a clinical syndrome that almost exclusively affects preterm babies. It is characterized pathologically by a hyaline membrane lining the alveoli and clinically by respiratory distress, which may be fatal. It results from maturational deficiency of lung surfactant. The clinical syndrome consists of tachypnoea, sternal recession and cyanosis, which are present from birth and worsen over the succeeding 24–48 h. The prevalence is inversely related to gestational age and has been estimated to be 15% in neonates born at less than 23 weeks of gestation [170]. Most deaths occur within the first 48–72 h. However, with the introduction of neonatal intensive

care, mortality is now rare in babies of more than 28 weeks' gestation. Full details should be sought in paediatric textbooks.

### **Aetiology**

In the newborn infant the alveoli are stabilized in order to allow gas exchange by the action of pulmonary surfactant, which is generated by type II pneumocytes. These cells synthesize and store surfactant from about 16–18 weeks of gestation [171]. By 24–26 weeks of gestation there is a 30-fold excess of stored surfactant compared with the lung surface area to be covered, and at this stage of gestation surfactant is released on to the alveolar surface. Fetal airways are fluid-filled and surfactant released into them is carried into the amniotic fluid, where levels can be measured to assess fetal lung maturity. In the absence of surfactant there is a tendency for the lung to collapse completely during expiration, which reduces the FRC and leads to a fall in dynamic compliance [172]. This is compounded by interstitial oedema that results from increased alveolar permeability [173]. Due to a reduction in lung compliance, the work of breathing is disproportionately increased, which eventually leads to diaphragmatic fatigue and respiratory failure [174]. Ventilation-perfusion mismatching occurs, partly as a result of airway closure, and dead space ventilation is increased and alveolar ventilation reduced. In addition there is an increase in right-to-left shunting through anatomical communications, which worsens hypoxaemia.

Gestational age is the single most important factor related to the development of RDS. However, one recent study has raised the possibility that there may be one or more human leucocyte antigen (HLA)-linked genes associated with an increased susceptibility, and may explain familial clustering [175]. Other factors associated with an increased risk of RDS are hypothermia, hypocalcaemia, hypoxia, hypovolaemia, asphyxia and shock.

### **Pathology**

The appearance of the lungs depends on the age of the infant [176]. Typically there is collapse of the alveoli, the lungs are completely airless and there is a prominent acidophilic membrane lining the respiratory bronchioles and alveoli, which are filled with proteinaceous exudate. There is interstitial and alveolar oedema and the pulmonary lymphatics are engorged. A hyaline membrane develops as a result of hypoxic injury to the type I and capillary endothelial cells, producing plasma leak into the interstitium and hence the alveoli, where a mixture of cells and protein forms a coagulum to produce the characteristic hyaline membranes in the alveolar spaces. Pulmonary vasoconstriction in areas of atelectasis also occurs.

### Functional abnormalities

As expected from the pathology, the lungs show low compliance. Minute ventilation may be increased but alveolar ventilation is decreased with increased  $V_D/V_T$  ratio and  $\dot{V}_A/\dot{Q}$  disturbance. In the early stages,  $P_{aO_2}$  and  $P_{aCO_2}$  may be only slightly lowered. Later there is gross hypoxaemia with acidosis and  $CO_2$  retention. Metabolic acidosis due to inadequate oxygenation of the muscles may occur. There may be systemic hypotension and a shunt through a patent ductus arteriosus potentiated by hypoxic arteriolar constriction. In addition, fetal haemoglobin, which binds more oxygen at a given  $P_{aO_2}$ , releases oxygen less readily to the tissues. Severe hyperkalaemia and hypercalcaemia may occur in infants who are hypothermic or who have occult cerebral haemorrhage. Hyponatraemia may be present in some infants, leading to complex effects on the immature kidneys. The excessive use of sodium bicarbonate to correct acidosis may also lead to hyponatraemia [177].

### Clinical characteristics and radiology

RDS begins from birth. The respiratory rate is raised, typically to around 100 breaths/min. Grunting and distressed respiration, flaring of the alae nasae, intercostal, supraclavicular and sternal respiratory retraction, tachycardia and cyanosis are manifestations of the fully developed condition. Auscultation reveals poor air entry but usually no crepitations. Oedema of the hands and feet is common. Respiratory distress increases for 24–48 h when a plateau is reached. Thereafter the signs and symptoms gradually improve, presumably because of surfactant production [178]. Survivors of uncomplicated RDS, usually in more mature babies, do not have an increased frequency of respiratory symptoms later in childhood and have been shown to have normal pulmonary function at school entry [179]. The chest radiograph shows diffuse fine granularity throughout the lungs. Later there is a more uniform opacification and the appearance of air bronchograms. More severely affected babies may continue to progress and to be dyspnoeic for many days or even weeks and may die.

### Diagnosis

The diagnosis can be presumed from the clinical features in a preterm baby with a characteristic chest radiograph. The diagnosis can be confirmed indirectly by measurement of surfactant activity in tracheal aspirates or amniotic fluid to assess fetal lung maturity. Two techniques are used, the lecithin–sphingomyelin ratio and the amniotic foam test, the latter helping to make the diagnosis more specific [180,181]. The differential diagnosis includes congenital pneumonia, typically caused by group B strepto-

cocci and which is radiographically indistinguishable from RDS [182], and transient hypoxaemia of the newborn, which closely mimics RDS clinically in the early stages but improves over the first 24–48 h [183]. In this condition the chest radiograph usually shows evidence of pulmonary oedema and may coexist with RDS.

### Prevention

Although a meta-analysis of prospective, randomized, controlled trials has demonstrated a reduction in RDS in babies whose mothers have been treated with corticosteroids, the use of these drugs is limited by the need for treatment for 36 h and this is not possible in over 50% of cases [184].

### Treatment

When a neonate at risk of RDS is born, prompt resuscitative measures should be initiated on the basis of the 1-min Apgar score [185]. Supportive treatment should be instituted, such as the maintenance of environmental warmth to prevent cold stress and the resultant increased oxygen consumption and aggravation of acidosis. Oxygen should be given sufficient to maintain a  $P_{aO_2}$  of 8–12 kPa (60–90 mmHg), since higher levels carry a risk of retrolental fibroplasia or pulmonary oxygen toxicity. When the blood pH is low this may be corrected, but not overcorrected, by intravenous bicarbonate. Close attention should be paid to fluid balance, serum calcium and glucose levels, and appropriate corrections made. Criteria for the ventilation of very ill babies have been developed, for example a  $P_{aO_2}$  of less than 5.3 kPa (40 mmHg),  $P_{aCO_2}$  greater than 11 kPa (82 mmHg) or pH less than 7.1 [186,187]. This strategy involves using a long inspiratory time to maximize mean airway pressure and thus improve oxygenation, while avoiding high peak pressures, which might contribute to barotrauma. Meta-analysis has shown the benefit of maintaining a short, as opposed to a long, inspiratory time [188]. CPAP has also revolutionized the management of these neonates, by improving oxygenation and preventing expiratory atelectasis [189]. High-frequency oscillatory ventilation and jet ventilation have also been shown to be both safe and effective in reducing lung injury [190]. Specific treatment is now available in the form of recombinant surfactant preparations, which can be instilled into the intratracheal tube. This treatment has been shown to improve prognosis in neonates with RDS [191,192]. Meta-analysis of 35 randomized controlled trials that used synthetic or natural surfactant have shown its benefit, although optimum dosage, timing and frequency of therapy have yet to be established definitively [193].

## Complications

Pneumothorax has been reported to occur in 15–35% of babies ventilated for RDS [194]. Pneumopericardium may also occur. Prompt intervention, with needle aspiration prior to insertion of a tube, may be life-saving.

Bronchopulmonary dysplasia, first described in 1967 and variously attributed to the severity of disease, oxygen toxicity and ventilatory assistance, is characterized by airways obstruction, poor clearance of secretions and chronic pulmonary oedema [195,196]. It is associated clinically with continuing retrosternal recession, tachypnoea and coarse crackles in the lung fields. Blood gases show CO<sub>2</sub> retention in addition to hypoxaemia. The chest radiograph shows patchy consolidation. Histologically the lung shows oedema, squamous metaplasia and fibroblastic proliferation. Despite these pathological findings, most affected infants survive, probably because the lung is still in a rapid phase of growth (see Chapter 56).

# PULMONARY EMBOLISM

DOUGLAS SEATON AND ANTHONY SEATON

The term 'pulmonary embolism' implies clinically significant obstruction of a part or the whole of the pulmonary arterial tree, usually by thrombus that becomes detached from its site of formation outside the lung and is swept downstream until arrested at points of intrapulmonary vascular narrowing. This concept of pulmonary embolism, which was attributed to Virchow 150 years ago [1], excites considerable clinical interest because despite improved understanding of its pathogenesis that has led to the widespread use of preventive measures, it is still a major cause of morbidity and mortality and its accurate diagnosis and effective treatment remain problematical. From the point of view of diagnosis and management, modern usage regards the pulmonary embolus and its formation in the venous system as one condition, venous thromboembolic disease.

## Prevalence

The reported frequency of pulmonary embolism in hospital patients coming to postmortem examination varies between series. Coon [2] reported pulmonary embolism as the cause of, or a major contributory factor to, death in 7–9% of necropsy cases. Another study using a postmortem pulmonary angiographic technique reported double this rate [3]. The true reported prevalence may be much higher when smaller antemortem thrombi are recorded at necropsy, others having found evidence of embolism in 60% of subjects [4]. Considering living patients, a recent report from a large general hospital indicated a prevalence of acute embolism of about 1% of all patients and as contributing to a fatal outcome in 0.2%. It also confirmed that the prevalence of undiagnosed pulmonary emboli in necropsies had not altered over several decades [5].

There is disagreement about whether or not the frequency of pulmonary embolism is increasing. There is little doubt that the condition is reported more frequently [6,7], but this may reflect increased awareness on the part of clinicians and improved diagnostic techniques. A study

that made a comparison between two series completed by the same pathologist showed no significant difference in the incidence over two periods covering the years 1945–55 and 1967–74 [8]. Extrapolations from such data have led to the belief that pulmonary embolism is a major contributory factor to death in 50 000–200 000 patients per year in the USA, with a considerably greater numbers suffering non-fatal events [9,10]. Care should be taken before applying data obtained after death to the living, for although pulmonary embolism is commonly found after death, this population is highly selected and the true incidence of pulmonary embolism in previously healthy people remains unknown.

## Mechanisms of thrombosis

Virchow in 1857 listed a triad of factors that he considered to predispose to the formation of thrombus in the venous system: (i) relative venous stasis, (ii) injury to the wall of a vein, and (iii) increased coagulability of the blood itself. The passage of over 130 years has proved these early general postulates to be remarkably durable and has allowed a more detailed examination of risk factors, with particular emphasis on the prevention of venous thrombosis.

Venous stasis allows local accumulation of platelets and clotting factors, especially thrombin, in the vein. Stasis may be promoted by increased viscosity, as occurs in polycythaemia and dehydration. It also commonly occurs as a consequence of immobility (because of lack of muscle pump activity in forcing blood up the leg veins), raised venous pressure in patients with cardiac failure and, less commonly, compression of vein by tumour or atheromatous arteries.

The normal venous endothelium possesses natural antithrombotic molecules, including heparan sulphate (which neutralizes thrombin), thrombomodulin (which inhibits thrombin) and plasminogen activator (which promotes local fibrinolysis). These, and the vasodilatory factors prostacyclin and nitric oxide, act to keep the

venous lumen patent, but may all be impeded when endothelial damage occurs.

The complex and delicate balance between blood coagulation and anticoagulation, modulated by thrombin, platelets and plasmin, may be altered in disease, obesity, after surgery and in trauma. It has been a matter of common observation that some people appear particularly prone to the development of venous thromboses, and it was shown in the 1970s that possession of blood group A appeared to be a risk factor [11]. It is now apparent that, at least in some cases, it is possible to detect individuals with increased susceptibility to thrombus formation on account of hereditary thrombophilia. This was originally noted in patients with autosomal dominant familial deficiency of antithrombin III which, although rare, carries a well-documented risk of recurrent deep venous thrombosis and pulmonary embolism and may be fatal. Antithrombin III is a protease inhibitor, with a very similar structure to  $\alpha_1$ -antitrypsin [12], and deficiency leads to defective inactivation of thrombin. The diagnosis may be established by immunological assay of plasma antithrombin III levels [13].

More recently, genetic deficiencies of the natural anticoagulants protein C and protein S have been described and these, together with antithrombin deficiency, are responsible for some 10% of venous thromboses occurring in younger people [14–18]. Even more common is an inherited resistance to activated protein C due to a mutation in the gene encoding factor V (so-called factor V Leiden mutation), which occurs in up to 5% of the normal population and which is now recognized as the most frequent explanation of familial thromboembolism [19]. In view of the complexity of the thrombin–plasmin systems, it would not be surprising if many more such genetic abnormalities promoting venous thrombosis were found in the future.

Coagulation factors are also altered in a wide range of disease states, for example as an acute-phase response and in malignant disease. In disseminated lupus erythematosus, chronic thrombocytopenic purpura and a number of other autoimmune diseases, an antiphospholipid antibody or 'lupus anticoagulant' may be found that paradoxically promotes clotting and is associated clinically with both venous and arterial thromboses [20].

Although venous thromboembolic disease may occur *de novo* as an apparently isolated phenomenon (and in these circumstances a primary or secondary thrombophilia should be suspected), the problem is usually multifactorial, particularly in hospital populations where it may be difficult to determine which of several contributory factors is predominant.

## Factors predisposing to thrombosis

### Immobilization

The formation of thrombus requires the local presence of activated clotting factors. With normal venous blood circulation these are not able to accumulate in sufficient quantities to initiate clot formation and are dispersed and cleared by the liver, their activity also being balanced by that of the fibrinolytic system. However, local venous stasis in the presence of activated clotting factors has been shown experimentally to result in the production of fibrin with thrombus formation.

Immobilization results in diminished muscle activity in the legs, which in turn reduces the rate of venous return [21] and increases the chance of deep venous thrombosis in both healthy individuals [22] and patients [23], the risk increasing in proportion to the duration of immobility [24]. Any local factors that immobilize leg muscles, such as the wearing of a plaster splint or muscular paralysis, increase the likelihood of thrombosis [25].

### Trauma

Both surgical and accidental trauma predispose strongly towards venous thromboembolism by the liberation of activated clotting factors and by the immobility that may result from the injury. An early analysis of thromboembolic deaths in accidental trauma cases found that femoral and tibial fractures were associated with the highest post-mortem incidence of pulmonary embolism, followed by pelvic, spinal and other fractures in diminishing order of frequency [26]. Severe burns also carry an increased risk of pulmonary embolism [2,26]. A more recent study of victims of major trauma has shown that venographic evidence of deep vein thrombosis occurred in 58% of patients; in 18% these thromboses were in the potentially dangerous proximal veins. The risk was greatest in injuries of leg and spine, and was increased by old age, need for blood transfusion and surgery [27].

Pulmonary embolism may account for about 15% of all postoperative deaths [28], leg amputations and hip, pelvic and spinal surgery having a relatively high incidence of venous thromboembolism [29,30]. Postoperative death after routine elective surgery, such as herniorrhaphy, cholecystectomy and hysterectomy, is most commonly caused by pulmonary embolism [31]. The type of operation used to achieve the same objective may also have an important influence on the likelihood of thromboembolic complications. Thus transurethral resection of the prostate and vaginal hysterectomy are both associated with a much lower risk of leg vein thrombosis than the same procedures carried out retropubically and abdominally [32].

The association of trauma with thrombosis is related

only in part to immobilization, since changes in coagulability also occur, with rises in factor VIII and fibrinogen, thrombocytosis and a reduction in fibrinolysis.

### Heart disease

Heart disease is a major risk factor in the genesis of venous thromboembolic disease in hospital, pulmonary embolism being over three times more common in patients aged 30 years and over dying of heart disease than an age-matched control group without heart disease or cancer [33]. This trend occurs irrespective of the aetiology of the heart disease, congestive failure and dysrhythmias being important contributory factors [34]. The majority of emboli arise in the veins of the legs rather than in the heart itself, probably as a consequence of reduced peripheral venous flow [2,35], although acute-phase increases in factor VIII, fibrinogen and antifibrinolysis occur after myocardial infarction.

### Malignant disease

Thrombophlebitis migrans was associated with gastrointestinal tract carcinoma over 125 years ago by Trousseau [36,37]. Since then many abnormalities of haemostasis have been demonstrated in patients with a wide range of cancers and different mechanisms appear to operate in different patients, including reactive increases in fibrinogen and expression by tumour cells of tissue factor and factor X. Not all neoplasms are associated with venous thrombosis; of those that are, pancreatic carcinoma is the most notable, followed in descending order of frequency by carcinomas of the bronchus, genitourinary tract, colon, stomach and breast [2]. The occurrence of venous thrombosis without obvious cause, especially if recurrent, should raise the possibility of a latent tumour.

### Pregnancy and the puerperium

Venous thromboembolic disease occurs more frequently in pregnancy and the puerperium than in age-matched non-pregnant controls and is the leading cause of maternal mortality in the UK. The reported incidence varies widely, from 1 in 200 [38,39] to 1 in 1400 deliveries, the latter figure being taken from a review of over 72 000 deliveries [40]. Thromboembolic events are more frequent in older multiparous women in the last trimester and puerperium (>35 yrs), and the incidence is further increased by Caesarian section [41]. Although fatal events are rare, occurring at a rate of 1–2 per 100 000 pregnancies [42], they have nevertheless been considered a major cause of maternal death [43,44]. The mechanisms for these observations include reduced venous return from the legs, which may result from direct pressure of the gravid uterus on pelvic veins, decrease in fibrinolytic activity and

increase in the levels of certain clotting factors [41,45,46], the act of parturition itself serving to trigger thrombus formation. However, it is now clear that hereditary thrombophilias are important in determining which women develop thrombotic disease during pregnancy and while on oral contraception [41,47,48].

### Oestrogen therapy

It is something of a paradox that oestrogen seems to be responsible for protecting women from thrombotic episodes as a result of increased fibrinolysis [49] yet oestrogen-containing oral contraceptives have been shown to increase the chance of venous thromboembolic disease significantly in otherwise healthy women. The increase in risk is proportional to the oestrogen content of the preparation and has been much reduced by the introduction of modern low-oestrogen pills, to the point that it is now generally accepted that the health benefits of oral contraceptive use outweigh the risks [50,51]. There is also evidence that risks are increased among women taking postmenopausal hormone replacement therapy. The relative risks appear to be increased about threefold, although the absolute risks are small, about 20–30/100 000 per annum [52–54], and in most cases are outweighed by the advantages of the therapy. Increased risks of thromboembolism are attached to the use of high-dose oestrogens, such as used in the treatment of carcinoma of the prostate [55]. The mechanism of thrombogenesis is unclear but depression of antithrombin III levels has been reported [56]. It is likely also that hereditary or acquired thrombophilic states, particularly the common factor V Leiden mutation, are important determinants of development of disease when taking oestrogen preparations [57,58].

### Other factors

Numerous other disorders have been claimed to carry an increased risk of thromboembolism. These include obesity [9], chronic bronchitis and emphysema [59], ulcerative colitis [33], diabetes mellitus [2], Cushing's syndrome [60], Behçet's syndrome [61], homocystinuria [62], polycythaemia rubra vera [63], essential and postsplenectomy thrombocythaemia [64,65], paroxysmal nocturnal haemoglobinuria [66] and Gram-negative sepsis [60]. Sickle cell disease also predisposes to pulmonary infarction and is discussed further in Chapter 53.

### Thrombogenesis and pulmonary embolism

Over 75% of pulmonary emboli originate from the veins of the lower extremities [67], probably arising as a result of the aggregation of small numbers of platelets usually in the vicinity of the venous valve sinuses. The release of

activated clotting factors may then result in a 'coagulation cascade', with the formation of red thrombus. This is normally removed by fibrinolysis or fixed by a combination of fibrinolysis and organization, the former process diminishing the bulk of the thrombus and permitting residual clot to be incorporated into the wall of the vein by an overgrowth of endothelium, which restores intimal continuity at the expense of producing incompetence of any venous valves that might be involved. The organization of established thrombus is thought to occur quickly, the process being completed within 7–10 days in a dog model [68]. In contrast to their arterial counterparts, venous thrombi occur more usually in the absence of any damage to the vessel wall, stasis being the most important initiating factor; however, there are exceptions to this rule, such as the trauma to the femoral vein that may occur during hip surgery.

Evidence exists to suggest that 60% of deep venous thromboses found at postmortem examination are associated with pulmonary emboli [24]. It would also appear that whereas thrombus may originate around a venous valve, propagation of clot occurs both proximally and to a lesser extent distally. The most common vessels of origin appear to be the plantar, common femoral and superficial femoral veins. Deep venous thrombi that propagate proximally tend to remain attached at their point of origin within the valve sinus but may contain a friable floating segment, consisting of red cells and platelets enmeshed in fibrin, that is liable to form an embolus by separating from its parent thrombus [69]. The length of such an embolus may vary greatly, from only a few millimetres to a coil of several centimetres that may be retrieved from the pulmonary artery in the necropsy room. When deep venous thrombosis is extensive, it is found to be bilateral in 80% of cases [24]. The majority of thromboses that present a serious threat to life detach themselves from the larger veins between the knee and the inguinal ligament [70]. Patients with thrombosis affecting the superficial veins of the leg (superficial thrombophlebitis) are not ordinarily considered to be at risk of pulmonary embolism from these veins [71] nor, curiously, are patients with axillary or subclavian vein thrombosis [70].

A small proportion of pulmonary emboli may arise in the pelvic veins, including the prostatic venous plexus in men, and also from the right side of the heart, both following myocardial infarction and in right ventricular failure due to a variety of causes [72]. Septic pulmonary emboli may arise from bacterial endocarditis in patients with septal defects, from the tricuspid valve in drug abusers, and from foreign material such as central venous lines, ventriculoatrial and arteriovenous shunts and pacemaker wires [73]. Such emboli present as recurrent febrile illness associated with patchy pneumonic shadows on chest radiography (Fig. 15.1), and are often misdiagnosed as pneumonia if the significance of the cardiac lesion is missed.

## Non-thrombotic pulmonary emboli

Material of extravascular origin may occasionally cause pulmonary emboli, although this is a relatively uncommon occurrence except in certain well-recognized situations [74].

*Fat embolism* is probably a common subclinical event following bony trauma [75,76]. Evidence of fat embolism was found in 39% of a group of 79 patients who died during the Korean War as a result of wounds and was considered to be a major cause of death in 10. Similarly, orthopaedic procedures involving the long bones risk displacing marrow fat into the circulation, and study of such patients by transoesophageal echocardiography has shown emboli passing through the heart in a high proportion [77]. In such circumstances complex pathological consequences may occur, including systemic embolization through a patent foramen ovale and activation of the clotting cascade with disseminated intravascular coagulation. Operations involving reaming of pathological lesions and cementing of hip arthroplasties seem to be those most likely to cause problems. Some series report clinically significant fat embolism in as few as 1–2% of long bone fractures, and in rather less than 1% of intramedullary operations [78], while others record up to 20% in cases of tibial and femoral fractures [79]. It seems likely that the syndrome may be detected very commonly in a mild form by those who look for it after appropriate trauma. Fat embolism is also a recognized complication of sickle cell disease and occurs as a consequence of bone infarctions [80].

Following such trauma, neutral fat may pass into the circulation from injured long bones, be carried to the lungs and become lodged in the pulmonary vasculature. Such neutral fat may be relatively innocuous [81], but hydrolysis to fatty acids is thought to result in local haemorrhagic tissue damage and pulmonary oedema. There may be a latent period of between a few hours and several days from the time of bony trauma to the onset of symptoms, and this may represent the time taken for the pulmonary injury to develop. In severe cases the patient presents with dyspnoea, hypoxaemia and hypotension; petechial haemorrhages, characteristically around the upper trunk and in the axillae, are a frequent accompaniment. The radiograph is often normal in spite of the dyspnoea, although evidence of adult respiratory distress syndrome may develop. Hypocalcaemia and anaemia may also occur. More rapid hypotension and death due to right ventricular failure have been described, possibly as a result of the mechanical obstruction of the pulmonary vasculature by a large volume of fat. The diagnosis is made on clinical grounds, and demonstration of fat in macrophages derived from bronchoalveolar lavage is no longer thought to be sufficiently specific to be worth doing [82]. There is no specific treatment and management is supportive.

Mechanical ventilation may be required. The subject of fat embolism has been reviewed in the orthopaedic literature [83].

*Tumour emboli*, which are usually microscopic, have been found in 2.4% of over 1000 necropsies carried out in patients dying as the result of solid malignant tumours [84]. A few of these subjects had been breathless in the absence of obvious lung parenchymal metastases. The condition may simulate thrombotic pulmonary embolism, particularly when larger pulmonary vessels are occluded by macroscopic emboli, but it differs in its lack of responsiveness to anticoagulation [85]. Tumours that have been implicated most frequently include carcinoma of the breast, stomach, colon and cervix, hepatomas, choriocarcinomas and hypernephromas.

*Air embolism* may be the result of faulty cannulation of the neck veins, therapeutic insufflation of air into a fallopian tube or intrauterine manipulations, including criminal abortion, in which a frothy solution may be introduced into the uterus under pressure. Small amounts of air are reabsorbed without harm but large amounts can cause mechanical obstruction of the pulmonary circulation and death. The subject of air embolism in diving is discussed in Chapter 57.

*Amniotic fluid embolism* is a rare but very serious complication of pregnancy [86,87]. It usually arises during labour or Caesarian section, but is not predictable or recognized as occurring because of any particular mishap. It causes respiratory distress with pulmonary oedema and shock. Maternal and fetal mortality have both been reported at 60%. It has been suggested that plasma zinc coproporphyrin concentrations in maternal plasma greater than 35 nmol/L indicate amniotic fluid in the blood [88]. Treatment is supportive, with ventilation if necessary to maintain  $P_{aO_2}$ .

## Pathophysiological response to pulmonary embolism

Pulmonary embolism results in the sudden obstruction of part of the pulmonary circulation and the pathophysiological response to this depends upon (i) the degree of reduction in the cross-sectional area of the pulmonary arterial tree, determined by the size and number of emboli, and (ii) the state of health of the myocardium and pulmonary parenchyma before the embolus [89].

### Cardiovascular effects

The mechanical obliteration of a part of the pulmonary arterial tree may be made worse by the release of vasoconstrictor substances such as serotonin from platelets contained within the embolus itself [90,91]. Although this loss of vasculature tends to increase pulmonary arterial resistance, the capacitance of the pulmonary circulation is such

that mean pulmonary pressure does not increase in the previously healthy lung until about 50% of the vascular bed is shut down [70]. Once this point is reached, the afterload on the right ventricle starts to increase and with it right ventricular end-diastolic pressure. If the mean pulmonary artery pressure exceeds 40 mmHg, which is the pressure required to maintain perfusion despite the loss of about three-quarters of the pulmonary vascular bed, then even a healthy right ventricle will fail. This produces a decline in pulmonary blood flow and in turn reduced filling of the left ventricle, which is no longer able to maintain a normal systolic blood pressure. This sequence of events occurs more readily in patients with pre-existing cardiopulmonary impairment [92] but otherwise only becomes evident if the pulmonary emboli are large or recurrent.

### Respiratory effects

Pulmonary embolism produces mismatching of ventilation and perfusion by preventing blood in the pulmonary artery from reaching the ventilated lung (increased alveolar dead space) and, paradoxically but perhaps more importantly, by interfering with the ventilation of lung that is still perfused (increased intrapulmonary shunting) [93]. This shunting results from (i) bronchoconstriction, (ii) alveolar collapse and (iii) pulmonary oedema. Various stimuli may produce bronchoconstriction following pulmonary embolism, the most important of which include alveolar hypocapnia arising in ventilated but unperfused lung [94] and the release of chemical mediators from platelets enmeshed in the embolus itself or from the surrounding lung. Alveolar collapse is due to loss of surfactant, which becomes deficient within a short time of embolism, causing alveolar instability. This in turn may result in those areas of atelectasis of sufficient size to be radiographically detectable (see below), and which may be haemorrhagic due to increased alveolocapillary permeability [95]. This increased membrane permeability may also result in a more widespread 'leaky lung', with consequent pulmonary oedema [70]. It is not surprising that the foregoing disturbances of cardiopulmonary physiology may combine to produce significant systemic arterial hypoxaemia in the presence of a large pulmonary embolus.

### Pulmonary infarction

Otherwise healthy lung tissue usually remains viable despite the interruption of the pulmonary arterial blood supply by embolism and pulmonary infarction is uncommon in such cases [96]. This is because the lung receives adequate oxygenation via the bronchial arteries and to a lesser extent the airways, and because an occluding embolus seldom completely obliterates the vessel

lumen [70]. When it does occur, infarction is more likely to be found with peripheral rather than central occlusions [96].

### Embolus resolution

It is common for large pulmonary emboli to fragment within a short time of impaction, and this may explain those cases in which profound hypotension and syncope occur but are of short duration [97]. As with venous thromboses, further dissolution of the embolus occurs within a short time as a result of fibrinolysis. There is evidence to suggest that when the embolus is composed of freshly formed thrombus dissolution may occur within a few days, whereas emboli formed from older thrombus may become organized into the pulmonary artery wall over a matter of weeks [70]. These mechanisms appear to be remarkably effective in restoring the patency of the pulmonary arterial tree to normal, provided that repeated emboli do not occur [98].

## Clinical features

### Deep venous thrombosis

A consideration of the clinical features and diagnosis of deep venous thrombosis in the legs is inseparably bound up with the subject of pulmonary embolism, as at least 75% of pulmonary emboli have their origin in the lower limb veins [67].

### Value of symptoms and signs

The symptoms and signs of deep venous thrombosis depend on inflammation of the vessel wall producing local pain, redness and heat (dolor, rubor and calor) and venous obstruction producing oedema. In fewer than 1% of cases of symptomatic deep venous thrombosis the leg suddenly becomes grossly swollen and tense both above and below the knee, and in this situation bedside diagnosis is likely to be accurate [99]. Unfortunately, however, in the large majority of cases the symptoms and signs are not so obvious and are non-specific to the point of being misleading. Diagnostic dilemmas arise because oedema and swelling may be associated with a paralysed limb or with heart failure, and pain (sometimes with swelling) may be produced by local trauma, muscular strain, calf haematoma, cellulitis, lymphangitis or a ruptured Baker's cyst, and may even occur after muscular cramps [100]. Despite the repeated observation, based on venography, that clinical judgement in the diagnosis of deep venous thrombosis is incorrect in about 50% of suspected cases [101], the results of a survey in 1982 showed that almost half of responding consultant physicians in Scotland relied only on physical signs in reaching the diagnosis

[102]. Furthermore, extensive involvement of the femoral vein by thrombosis may be present in the absence of any symptoms or signs since, provided that the superficial venous system and lymphatics are competent, oedema need not occur unless thrombus extends as far as the saphenofemoral venous junction. This accords with the frequent absence of bedside signs of venous thrombosis in patients with pulmonary embolism. In spite of this generally pessimistic view of the likelihood of making a clinical diagnosis, the odds of being right may be improved by considering a number of major and minor factors in order to arrive at a probability score [103]. On the aetiological side, major factors are active cancer, paralysis or immobilization of a leg, more than 3 days in bed or major surgery within 4 weeks, and a strong family history of venous thrombosis; major signs are tenderness over the leg veins and swelling of calf and thigh, or more than 3-cm swelling of calf. Minor evidence includes recent trauma, oedema, dilated veins and erythema of the symptomatic leg. The suggested method of clinical assessment is shown in Table 25.1, which is derived from Wells *et al.* [103].

Once made on clinical grounds, the diagnosis of deep venous thrombosis is rarely rejected in the absence of venography or other diagnostic tests. Because clinical diagnosis alone has a high false-positive rate, failure to

**Table 25.1** Clinical method for predicting probability of deep venous thrombosis.

---

#### Checklist

##### Major points

- Active cancer
- Paralysis or plaster lower limb immobilization
- Recently in bed >3 days or major operation within 4 weeks
- Localized tenderness along distribution of deep leg veins
- Both thigh and calf swollen
- Calf swelling >3 cm asymptomatic side, 10 cm below tibial tuberosity
- Family history of deep venous thrombosis in two or more first-degree relatives

##### Minor points

- History of trauma to symptomatic leg within 60 days
- Pitting oedema in symptomatic leg
- Dilated superficial veins in symptomatic leg (not varicose)
- Hospitalization in last 6 months

#### Clinical probability

##### High

- Three or more major points and no alternative diagnosis
- Two or more major, two or more minor and no alternative diagnosis

##### Low

- One major, two or more minor plus alternative diagnosis
- One major, one or more minor plus no alternative diagnosis
- Three or more minor plus alternative diagnosis
- Two or more minor plus no alternative diagnosis

##### Moderate

- All other combinations
-

make proper use of ancillary diagnostic tests commits large numbers of patients to the potential hazards of prolonged anticoagulation and to the social and financial disruption of an unnecessarily prolonged treatment period [104]. It is therefore desirable to have a strategy for further investigation if the condition is suspected. The tests available are venography, impedance plethysmography and ultrasound.

Venography is generally taken as the gold standard but is less comfortable for the patient. When the injection is made in the foot veins, it can show the entire deep venous system of the leg. Demonstration of pelvic veins depends on the now rarely used bilateral femoral intratrochanteric injection method, which usually is done under anaesthetic. Impedance plethysmography and Doppler ultrasound methods, although based on different physical principles, both depend upon venous outflow from the leg being obstructed by extensive venous thrombosis. Both make use of an additional artificial obstruction to venous outflow by the application of either an inflatable cuff or manual compression. This produces pooling of blood in the leg veins, and when the obstruction is suddenly released the speed with which pooled blood leaves the leg is slowed by the presence of thrombus in veins in the thigh and above.

### Venography

Ascending venography as described by Rabinov and Paulin [105] is the accepted reference standard in the diagnosis of deep venous thrombosis [106] and its use has increased with the growing awareness of the unreliability of diagnosis based on history and physical examination alone. The technique requires the injection of a radio-opaque contrast medium into a vein, usually on the dorsum of the foot, under fluoroscopic vision (Fig. 25.1). It has the advantage of visually demonstrating thrombus in a vein. It has the disadvantage of being an invasive test that may be painful and in a small percentage of patients is associated with systemic reactions to the contrast medium [107]. Local reactions may occur as a result of extravasation of contrast into subcutaneous tissues and endothelial damage may lead to superficial thrombophlebitis and even deep venous thrombosis in a few patients in whom the venogram was previously normal [107]. This investigation requires a high degree of technical and interpretative skill is required in order to obtain an adequate result. In less experienced hands, artefacts produced by non-opacified blood flowing from a small vein into a larger opacified vessel may be misinterpreted as thrombus. An intraluminal filling defect that remains constant on different projections and during a Valsalva manoeuvre is regarded as positive proof of thrombus. The failure of a segment of the deep venous system to fill properly is suggestive of thrombosis but may be artefactual, in which

case a false-positive diagnosis of deep venous thrombosis may be made. The various disadvantages of this test have to be set against the risks of unnecessary anticoagulation in large numbers of patients [108].

### Impedance plethysmography

This test is based on the physical principle that changes in blood volume in the calf result in changes in electrical impedance (resistance) to the passage of a known current across the calf muscles. These changes in blood volume and therefore in impedance are reduced by the presence of thrombus in the popliteal vein and in veins proximal to it [109].

The patient lies supine with the leg elevated to about 25° and the knee slightly flexed. An occlusive pneumatic cuff 15 cm wide is applied to mid-thigh and inflated to a pressure of 45 mmHg for 2 min. The original method made use of a maximum respiratory effort to produce flow changes [110] but this technique is unreliable and has been superseded by the occlusive cuff method. Changes in electrical impedance are detected by circumferential calf electrodes and recorded electronically. Sequential readings are made in order to achieve maximal venous filling. The change in impedance during cuff inflation (reflecting venous capacitance) is plotted along the horizontal axis of a graph, and the change in impedance during the first 3 s after cuff deflation (indicating venous outflow) is plotted on the vertical axis. The intersection point of the two readings on the graph is read as normal or abnormal according to whether it falls above or below a straight line obtained from testing large numbers of patients with normal venograms [109,111].

This test is non-invasive and easy to apply being a safe alternative to venography [112]. It is sensitive to obstruction above the knee, which is the site from which most emboli break off, although less so than compression ultra-sound. It is insensitive to calf thrombi that produce relatively little venous obstruction, and this may produce false-negative results. False positives are uncommon but may be produced by incorrect positioning or by isometric muscle contraction, which can result in venous constriction in anxious patients but which may be detected by the incorporation of an electromyography electrode into the recording device. Further false-positive values may be produced as a result of venous compression by an extravascular mass, in congestive cardiac failure and in severe arteriosclerosis affecting the legs.

### Compression Doppler ultrasound

This test uses the physical principle of the apparent change in frequency (pitch) of a source of sound when it is moving relative to a stationary observer (Doppler effect).

**Fig. 25.1** Contrast venography showing finger of thrombus extending up femoral vein. (Courtesy of Dr Lesley Gomersal.)

In practice the 'source' of ultrasound is an electrical oscillator and a piezoelectric crystal contained in a hand-held probe. The 'moving object' is the column of blood cells contained in the vein over which the probe is held. The 'stationary observer' is a second piezoelectric crystal, also contained in the probe, that receives a reflected beam of ultrasound. If the column of blood is stationary, then the apparent frequency of the reflected beam equals that of the incident beam and no signal is recorded. However, movement of the column of blood results in the ultrasound beam being reflected at an apparently different frequency, the change of which is proportional to the rate of flow of the blood. This difference in frequency may be amplified to produce an audible signal [113].

The test is performed with the patient in a semi-recumbent position and free from the compressive effects

of corsetry. When the probe is placed over the femoral artery and moved medially, a typical low-pitched flow sound is produced by blood in the femoral vein. Normally the pitch of the sound varies cyclically with respiration but obstruction to venous flow above this level may abolish this cyclical variation. Manual compression of the vein proximal to the probe also reduces the signal, which in normal subjects is briefly augmented and then restored when the compression is suddenly released, whereas in proximal venous obstruction this augmentation may be reduced or abolished. Similarly, squeezing of the calf or thigh muscles may also produce augmentation of the flow signal in normal subjects, whereas this does not occur in those with venous thrombosis that significantly reduces flow rates. The patency of the superficial femoral vein may be examined by following its course with the probe, with

alternate use of proximal muscle compression with sudden release and distal muscle squeezing. The popliteal vein may be studied by compression and sudden release of the thigh muscles and by squeezing the calf, and the posterior tibial vein by compression and release of the calf and by squeezing the foot.

Although Doppler ultrasound depends heavily on the experience of the observer, technical advances and increased availability have made it the preferred non-invasive modality for symptomatic deep venous thrombosis, with greater overall sensitivity than impedance plethysmography. It is sensitive to proximal thrombosis in the popliteal veins and above, but suffers the same deficiencies with regard to the detection of calf vein thromboses [114], although these may be better displayed with the use of colour Doppler [115].

### Other tests

The radioactive fibrinogen test depends upon  $^{125}\text{I}$ -labelled fibrinogen being incorporated into actively forming thrombus so that it can be detected using a surface counter. It has been a useful research tool in objectively determining by serial measurements the frequency with which venous thrombosis occurs in high-risk groups such as surgical patients, and used in this way it may detect approximately 90% of acute calf vein thrombi.

The test is carried out by injecting 4 mBq of labelled fibrinogen into an arm vein; 100 mg of sodium iodide may be given intravenously 30 min beforehand to block the uptake of radioactivity by the thyroid. Recordings may be made at the bedside from 2 h to about 1 week after injection, the leg being elevated  $15^\circ$  above the horizontal to prevent calf vein pooling. The portable rate meter gain is adjusted to read 100% over the heart, and recordings are then made at 8-cm intervals down the course of the femoral vein in the thigh and from the popliteal fossa down the posterior aspect of the calf. The presence of uptake is indicated by a repeatable 20% or more difference in readings between adjacent points on the same leg or between corresponding points on the opposite leg. An experienced operator takes less than 15 min to carry out the examination.

The major disadvantage of this test is that patients in whom the diagnosis of deep venous thrombosis is suspected clinically may already have well-established thrombus, in which the radioactive fibrinogen becomes incorporated only very slowly so that positive readings may take 24–72 h to achieve or may not occur at all if anticoagulation has been started. A further problem is the unreliability of fibrinogen scanning over the upper thigh and pelvis due to high counts from pelvic vessels and the bladder, although this drawback is offset by the general belief that pelvic and upper thigh vein thrombosis is unusual in the absence of calf vein thrombosis [32]. The

radioactive fibrinogen uptake test is contraindicated in pregnancy and during lactation and it has to be remembered that its prior use invalidates a lung scan should this also be required. False-positive results may occur in the presence of local trauma, inflammation or haematoma formation.

Various blood tests have been used to detect recently formed thrombus and these include the detection and measurement of fibrinogen degradation products [116] and the measurement of D-dimer, the split product of fibrin [117]. The former test lacks sufficient sensitivity and specificity to be routinely applicable, but the latter has shown some promise as a quick test in order to screen out suspected venous thrombo-embolic disease (see p. 730) [118, 119].

### Diagnostic strategy

A patient with a leg that becomes suddenly and uniformly swollen and tense from top to bottom has a deep venous thrombosis and can be treated as such without more ado. Relatively few patients fall into this category and the diagnostic pathway followed depends to a large extent on the facilities and expertise available locally. Investigations should not be contemplated unless there are leg signs or unless pulmonary embolism is suspected. The clinical suspicion may be graded as high, medium or low based on the features mentioned above [103]. In any case a non-invasive test should be carried out, and increasing confidence can now be placed in the use of ultrasonography, which has been shown to be both more sensitive and more specific than impedance plethysmography in the detection of the dangerous proximal thromboses [120]. If this is positive in the presence of clinical evidence, treatment should proceed. If it is negative despite strong clinical suspicion, contrast venography should be carried out as this demonstrates the calf veins as well as those more proximal. In experienced hands venography is efficient in diagnosing or excluding deep venous thrombosis and can be used as a front-line test [121], if the extra inconvenience and slight risk of side-effects are acceptable. In cases where clinical suspicion is low, there is no evidence of pulmonary embolism and ultrasound is negative, it is reasonable to withhold or discontinue anticoagulation. Since the objective of seeking deep venous thromboses is to prevent pulmonary emboli, if suspicion remains after a negative ultrasound scan a reasonable strategy is to withhold anticoagulants but to repeat the scan after 1 week to ensure that any undetected calf vein thrombosis has not spread into the popliteal or femoral veins whence the risk of embolization is high. This strategy has been shown to be effective in preventing embolism and to be cost-effective [122, 123]. A suggested diagnostic pathway is illustrated in Fig. 25.2. It will be noted that this scheme recommends venography if the point score indicates 'low risk' but the

ultrasound is abnormal, as it was found that venography showed the ultrasound false-positive rate to be substantial (37%) in this group [123].

## Pulmonary embolism

### Clinical presentation

Pulmonary embolism may present in many guises, sometimes with catastrophic and fatal suddenness and sometimes with gradually worsening breathlessness, so that the precise timing of the onset of the illness cannot be recalled.

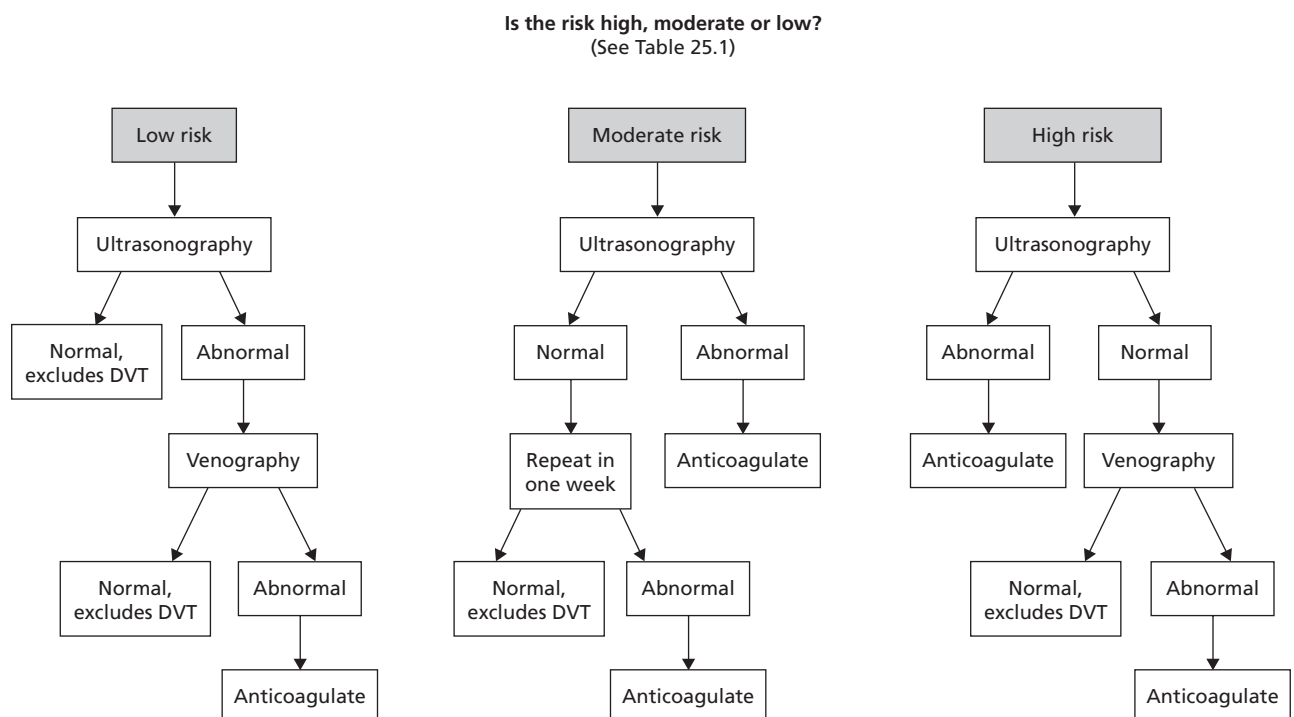

Massive pulmonary embolism occurs classically a week or more postoperatively or following some other period of immobilization. It may be immediately preceded by straining, such as during defecation, or by other minor physical exertion, such as that involved in getting out of bed or even laughing. When death occurs suddenly, it is likely to result from the profound hypotension associated with an abrupt cessation of pulmonary venous return to the left side of the heart. Those episodes in which syncope is followed by recovery of consciousness may be regarded as 'near misses', a major embolus fragmenting and passing away from the main pulmonary outflow tract

into more peripheral lung vasculature and allowing the re-establishment of sufficient left ventricular filling to prevent immediate death. These patients are dyspnoeic, restless, anxious, confused and cyanosed, with hypotension and tachycardia. Central chest pain as a result of reduced coronary artery perfusion may also occur.

Many patients with pulmonary emboli present in a more insidious manner, their symptoms resulting from smaller often recurrent emboli. Breathlessness is the most common symptom in this group and it may be incorrectly attributed to heart failure, emphysema or even to emotional instability. Supporting symptoms, such as cough, haemoptysis and pleuritic pain, may be absent, although when present may be wrongly ascribed to bacterial infection with pleurisy. Dyspnoea and pleuritic chest pain were the most common symptoms in an angiographically documented series of over 300 patients [34]. None of these symptoms are specific and the diagnosis should be considered in any patient in whom the level of breathlessness does not appear to be explained satisfactorily by coexisting disease. Suspicion should mount in the presence of supporting symptoms and when the patient is at increased risk, whether because of recent surgery, immobility or those other predisposing factors previously discussed.

Physical examination may reveal varying degrees of breathlessness with tachypnoea. Inspiration may be seen to produce pain due to pleuritic involvement and the patient is usually able to help the physician localize the site of this pain accurately. A pleural rub is often heard at

Fig. 25.2 Deep venous thrombosis: diagnostic pathway. (After Wells *et al.* [123].)

this point, if not during tidal breathing then on deeper inspiration, the effort of which may make the patient wince. With large emboli, tachycardia and a gallop rhythm are usual. Breathlessness is present both lying and sitting but is associated with no auscultatory signs in the lung, a most important negative feature. Jugular venous engorgement is usual but an accentuated pulmonary component of the second heart sound depends on the degree of pulmonary hypertension produced and whether the right ventricle can maintain its output against increased resistance. Occasionally wheeze may be heard as a result of secondary bronchoconstriction [124]. Pyrexia may be present and is very occasionally the dominant finding until anticoagulation is commenced. The syndrome of multiple pulmonary emboli leading to cor pulmonale is discussed in Chapter 26.

Although pulmonary emboli usually arise from the deep venous system in the legs, clinical signs of deep venous thrombosis are obvious in fewer than one-third of patients [124].

### Diagnostic confirmation

In most patients treated for pulmonary embolism it is evident that the diagnosis has been based on clinical suspicion in a patient sufficiently ill to merit anticoagulation while investigations are undertaken to substantiate the diagnosis. The order in which investigations are carried out is bound to depend upon their availability in the hospital but also on the circumstances of presentation and admission. It is usual for less definitive tests to be carried out first because they provide useful information, albeit of a negative nature, in excluding other possible diagnoses and in monitoring the patient's cardiopulmonary function. Furthermore, they are readily available to the admitting doctor and are relatively inexpensive.

### Electrocardiography and echocardiography

The ECG is usually abnormal in massive pulmonary embolism, but much less frequently in other circumstances [125]. There is often sinus tachycardia. Atrial fibrillation may occur, as may a bundle branch block, usually right. The limb leads occasionally show the much-quoted S1Q3T3 pattern and, most helpfully, T-wave inversion may be found in the anterior chest leads implying right ventricular strain. This change implies a large embolic event (Fig. 25.3). In severe cases, this pattern is associated with prolongation of the QRS complex, mimicking right bundle branch block. When the clinical features raise the suspicion of a pulmonary embolus but the ECG shows changes of a myocardial infarction, it should be remembered that it is not uncommon for the former condition to complicate the latter.

Echocardiographic findings may assist in the diagnosis

of major central pulmonary embolism, particularly when the cause of sudden hypotension and tachypnoea is unclear. In such cases it may show changes of acute right heart strain with ventricular hypokinesia and tricuspid regurgitation from which pulmonary artery pressure may be estimated [126].

### Chest radiography

It is often impossible to obtain good quality posteroanterior films in an ill patient, and the chest radiograph may simply serve to exclude other gross focal pulmonary pathology. When adequate technical results are achieved, the chest film in pulmonary embolism is frequently normal [127]. Paradoxically, this may be a most useful investigative finding in an acutely breathless patient in whom pulmonary embolism is suspected, since when coupled with consistent ventilation-perfusion lung scan findings and provided that there is no history of previous cardiopulmonary disease to account for them, the combination of a normal chest film and abnormal isotope scan is diagnostic of pulmonary embolism.

When the chest radiograph is abnormal, there are no findings that can be cited as pathognomonic of pulmonary embolism [128]. Non-specific infiltrates of virtually any configuration may occur and very few, if any, are wedge-shaped. These infiltrates, which need not be confined to the lower zone, usually abut a pleural surface and are dome-shaped (Fig. 25.4), although this need not be

**Fig. 25.3** ECG of patient with acute massive pulmonary embolus: (a) on admission, showing S1Q3T3; (b) following day, showing progression to right bundle branch block pattern with inverted T waves in anterior chest leads.

evident on a single projection. They probably represent areas of haemorrhagic atelectasis, hence their tendency to clear sometimes within a matter of a few hours. Those infiltrates in which true pulmonary infarction occurs are less likely to resolve radiographically and ultimately may be marked by a thin 'fibrotic' band shadow (Fig. 25.5). Elevation of a hemidiaphragm may occur with or without pulmonary infiltration and is indicative of ipsilateral volume loss. This is due to a combination of diminished pulmonary blood volume, localized bronchoconstriction and partial atelectasis. An avascular lung in association with consistent clinical features was described by Westermarck in Boston in the 1930s. It is an uncommon sign of massive embolism but is as close as the chest film gets to confirming the diagnosis when it occurs (Fig. 25.6). A pleural effusion, if present, is frequently haemorrhagic, although the cell and protein contents are too variable to be of any diagnostic assistance [129]. Other findings, such as an enlarged proximal pulmonary artery trunk or distal pulmonary oligoemia, are highly subjective and unreliable diagnostic signs.

### *Arterial blood gas analysis*

Arterial blood gases are of more therapeutic than diagnostic value in pulmonary embolism. While a reduced  $P_{aO_2}$  and  $P_{aCO_2}$  are characteristic, they are entirely non-specific findings. Furthermore, a normal  $P_{aO_2}$  does not exclude pulmonary embolism [124,130] and is not unusual in patients with no pre-existing cardiopulmonary disease. Pulmonary embolism cannot therefore be excluded on the basis of a normal arterial blood gas estimation, and earlier reports of the diagnostic usefulness of this test may mislead [131].

### *Plasma D-dimer and other blood tests*

Plasma D-dimer has been mentioned in relation to the diagnosis of venous thrombosis. Various ELISA assays are available as is a rapid bedside whole blood latex test which requires a visual reading with the potential for interobserver disagreement. The test has a low specificity with too many false positives to be diagnostically useful. False negative results are however unusual so the true high negative predictive value of the test may allow its

incorporation into algorithms designed to exclude venous thromboembolism [118,119].

Other tests are mentioned largely to be dismissed, as individually they have no discriminatory value [34]. They include the presence of a leucocytosis and elevated erythrocyte sedimentation rate, plasma lactate dehydrogenase and bilirubin levels.

#### *Lung ventilation–perfusion ( $\dot{V}/\dot{Q}$ ) scans*

The  $\dot{V}/\dot{Q}$  lung scan remains the screening investigation of choice in most institutions for patients with suspected pulmonary embolism, although there is an increasing trend for the substitution of spiral CT. Lung perfusion scans are usually carried out using macroaggregates of human albumin that have been labelled with radioactive technetium-99m. A suspension of these particles (diameter 10–50  $\mu\text{m}$ ) is injected intravenously with the patient recumbent so that they behave as microemboli, becoming arrested in the pulmonary capillaries and precapillary arterioles. The ionizing radiation that they emit remains detectable for up to 2 h by means of a large-field gamma camera, from which scintigrams are produced that represent the distribution of pulmonary arterial perfusion. A normal scan shows a homogeneous distribution of activity throughout six views: anterior, posterior, left and right lateral and left and right posterior oblique (Fig. 25.7).

Lung perfusion scans are extremely sensitive in detecting blockage of vessels of diameter 3 mm and more, to such an extent that validated reports of angiographically detected pulmonary emboli in patients with normal per-

fusion scans are extremely rare [132,133]. A negative perfusion scan in a patient with suspected pulmonary embolism therefore virtually excludes this diagnosis. The most serious drawback of a positive perfusion scan is its lack of specificity [134], in that many common pulmonary disorders, such as pneumonia, asthma and emphysema, may produce perfusion defects that are indistinguishable from those seen in cases of pulmonary embolism. This is true to the extent that when a perfusion defect is seen that corresponds to a focal abnormality on the chest radiograph, then the result of the scan neither confirms nor excludes pulmonary embolism and must be regarded as indeterminate. For this reason it is common practice in most centres to also carry out a ventilation scan. Xenon-133 labelled air or technetium aerosols are often used for this although Krypton-81m is an alternative, this gas having a very short (13 s) half-life allowing multiple plane, higher resolution imaging.

$\dot{V}/\dot{Q}$  scans (Fig. 25.8) should be reported by experienced observers according to validated criteria, such as those adopted in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) project [135]. This, and other studies, using pulmonary angiography as the gold standard, found that a 'high probability'  $\dot{V}/\dot{Q}$  scan report correctly diagnosed pulmonary embolism in about 92% of cases, whereas the PIOPED frequency of pulmonary embolism in 'low probability' scans was 16%. Unfortunately, even with good technique, more patients fall into an 'indeterminate' or equivocal  $\dot{V}/\dot{Q}$  scan category than into the high or low probability categories. The results of  $\dot{V}/\dot{Q}$  scanning should therefore be interpreted in the light

(a)

(b)

**Fig. 25.6** (a) Chest film of patient with acute cor pulmonale due to embolism showing unperfused right lung (Westermarck's sign). (b) Perfusion scan the same day confirming the lack of perfusion on the right, together with smaller left-sided defects.

of the clinical characteristics of the patients in order to make best use of the technique and an integrated diagnostic strategy (see p. 734), using as much relevant clinical information as is available should be followed [136,137].

Ventilation scans need not be carried out if the perfusion scan is normal or if it shows 'high probability' changes and the chest radiograph is normal in which case the diagnosis of pulmonary embolism is secure [138]. The 'low probability' interpretation on  $\dot{V}/\dot{Q}$  scans carried out in patients

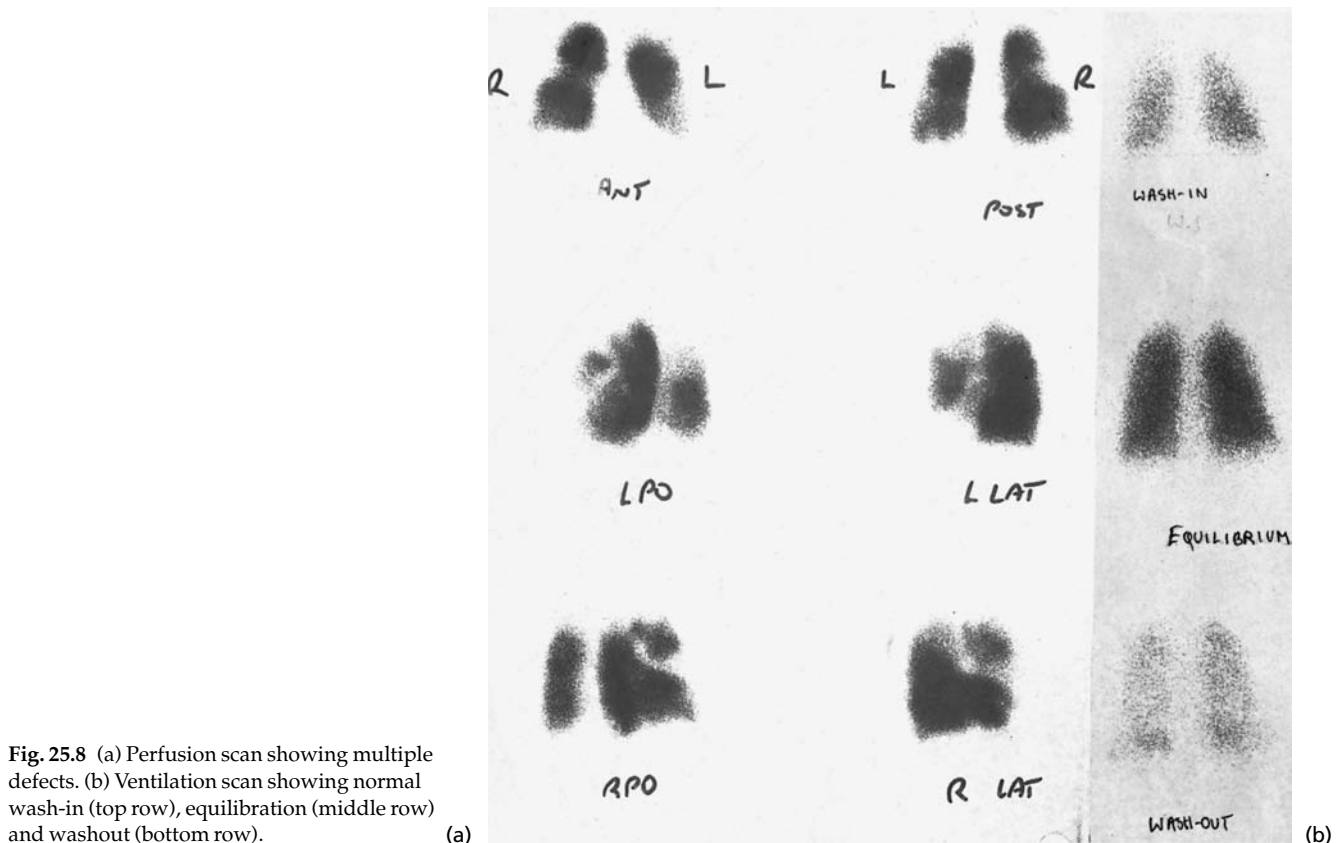

with 'poor cardiorespiratory reserve' has been shown to underestimate pulmonary embolism so that such reporting in this category of patient should be avoided or, if made, regarded as equivocal [139].

Provided that the limitations of  $\dot{V}/\dot{Q}$  scanning are understood, this method of investigation is still extremely useful in not only excluding but also diagnosing pulmonary embolism and will remain so until such time as newer investigations, such as spiral CT, have been more fully validated and become more widely available.

### *Pulmonary angiography*

Pulmonary angiography is the classic way to demonstrate pulmonary emboli radiographically. It is regarded as the 'gold standard' in the diagnosis of pulmonary embolism and is the method by which other investigative procedures are assessed [134]. The most satisfactory technical results require the placement of a cardiac catheter in the pulmonary artery trunk or in one of its branches in order to allow the selective injection of contrast material [140]. The catheter may be inserted through an antecubital fossa cut-down or percutaneously via the internal jugular or femoral vein, although the latter route carries the risk of dislodgement of venous thrombus. It is necessary for the radiologist to be prepared to take oblique as well as supine views in order not to miss an embolus [141], and the patient has to be sufficiently cooperative to remain immobile during the procedure. Pulmonary artery pressure may be measured using a simple manometric or other system. Positive evidence of pulmonary embolism is provided by the finding of abrupt termination of pulmonary vessels and by the presence of intraluminal filling defects (Fig. 25.9). The latter finding is the most common and reliable diagnostic criterion [34,70] and false-positive results should be rare. False-negative results are also rare. A study of 180 patients in whom a diagnosis of pulmonary embolism had been made clinically but in whom angiography was normal showed that during a 6-month period

of follow-up without anticoagulation no patient had a further clinical event suggestive of embolism, and of those who died no evidence of embolism or infarction was found at autopsy [142]. Needless to say, the diagnostic accuracy of the procedure is a function of the skill and experience of the medical practitioner performing it and, even among experts, there are inevitable interpretational disagreements, although these are significantly fewer than is the case with isotope scanning [131]. The mortality of the investigation in experienced hands is about 0.2–0.5% [134,140,143,144]. These deaths tend to occur in patients with cor pulmonale, in whom special caution needs to be taken with regard to the volume of hypertonic contrast medium used and the rate of injection. The morbidity is 1–3% and includes such complications as cardiac perforation, serious ventricular dysrhythmias, renal failure and hypersensitivity to the contrast medium [143,144]. The investigation is contraindicated in patients with a history of either a recent myocardial infarction or a propensity to ventricular dysrhythmias. From this discussion it is clear that pulmonary angiography is unnecessary in patients who have had a normal six-view lung perfusion scan, which effectively excludes the diagnosis.

Pulmonary angiography is mandatory if pulmonary embolectomy is proposed and is strongly recommended if the patient is to be subjected to any form of vena caval interruption or to treatment that carries a greater than

**Fig. 25.9** Pulmonary arteriogram showing large emboli in left upper and lower lobe arteries and in right upper lobe artery.

usual risk of bleeding, such as fibrinolytic therapy or standard anticoagulation in the presence of peptic ulcer disease. It has also been previously recommended in patients where lung scan results are equivocal for embolism in order to reduce the chance of unnecessary anticoagulation, with its attendant morbidity and mortality [145]. More recent diagnostic strategies have been developed, however, using serial non-invasive leg investigations for deep venous thrombosis in order to reduce the need for pulmonary angiography in this group of patients (see below) [150].

The timing of pulmonary angiography in relation to an acute episode of embolism is not critical. Complete resolution of a large pulmonary embolus within 2 weeks has been reported but is probably unusual [146], there being little experimental evidence to support rapid dissolution, so that angiography within a week of the episode may still demonstrate thrombus [140].

#### *Other radiological techniques*

Digital subtraction angiography, using injection of relatively small amounts of contrast material either intravenously or through a flow-directed balloon catheter, is a procedure capable of producing good images in a relatively short time [147,148]. While it is associated with few complications and is used in some centres in place of angiography, it cannot yet replace it as the gold standard

for diagnosis. Contrast-enhanced spiral CT has also been used to demonstrate major vessel emboli [148]. While it has not yet been shown to have the sensitivity and specificity to replace angiography [138,149], as a safe and non-invasive procedure it is reasonable to suppose that it will soon become the investigation of choice, particularly once thinner section techniques have become increasingly available and more fully validated. It is capable of demonstrating embolus down to segmental pulmonary arteries (Fig. 25.10) but reservations have been expressed while data comparing spiral CT with pulmonary angiography are relatively sparse [149].

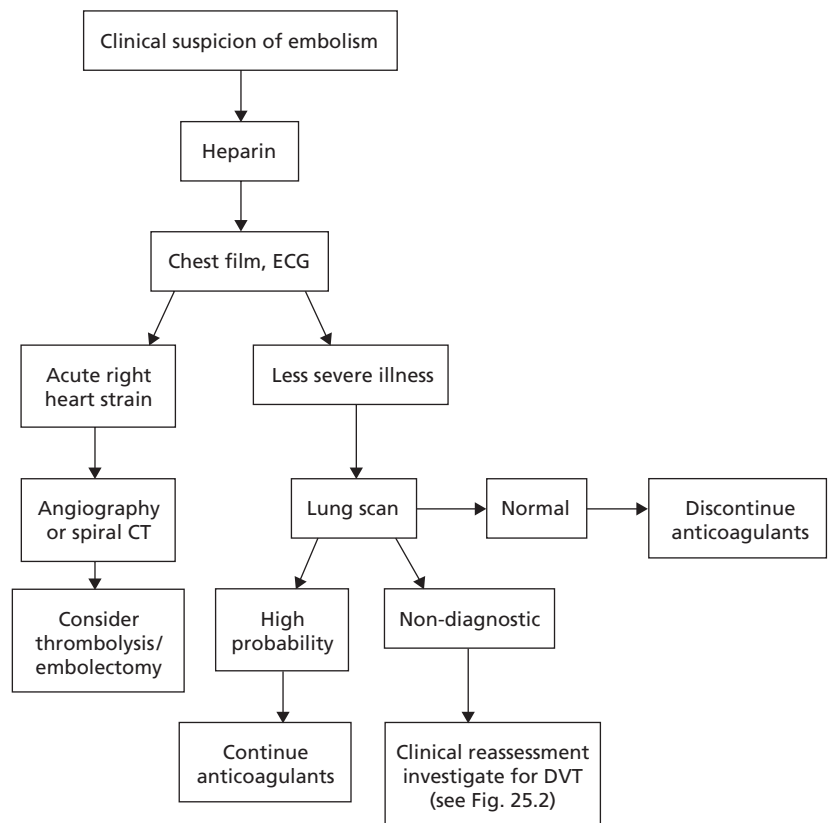

#### **Diagnostic strategy**

The strategy for diagnosis of pulmonary embolism should combine both clinical and investigative probabilities [150,151] (Fig. 25.11). On clinical suspicion of pulmonary embolism a chest radiograph and ECG are obtained. If the patient is severely ill and thrombolysis or embolectomy being considered, angiography (or, in centres with appropriate experience and equipment, contrast spiral CT) should be performed immediately. Echocardiography may provide 'stop-gap' surrogate evidence of the diagnosis. In other circumstances, provided that the chest film shows no obvious alternative pathology, anticoagulants are started while further investigation proceeds with a ventilation-perfusion isotope lung scan. If a six-view

**Fig. 25.10** Spiral contrast-enhanced CT image of emboli (arrowed) in right main and left lower lobe pulmonary arteries.

**Fig. 25.11** A diagnostic strategy for suspected pulmonary embolism (see text).

perfusion scan is normal, the diagnosis of pulmonary embolism has been excluded and anticoagulants should be stopped. When the isotope scan shows a high probability of pulmonary embolism (lobar perfusion defects or multiple segmental perfusion defects with normal ventila-

tion in corresponding areas), then the diagnosis is sufficiently firm for treatment to be continued without further invasive investigation. If the ventilation-perfusion scan is non-diagnostic, showing only small or matched defects (as is likely in the presence of an abnormal chest radi-

ograph due to coexisting disease), then after clinical reassessment compression ultrasonography or venography may be carried out while treatment is continued. If either of these two approaches gives a positive result for venous thrombosis, then this alone provides significant grounds for continuance of treatment with anticoagulants. However, if the result is negative then the argument for discontinuing anticoagulation and setting an alternative diagnosis is strong.

## Management

The spectrum of thromboembolic disease ranges from a patient with a sore calf or unexplained episode of chest pain to acute severe dyspnoea and cardiorespiratory collapse. In all cases, once the diagnosis is suspected and its likelihood confirmed by the above tests, treatment is likely to be necessary. The drugs available are the anticoagulants heparin, including its low molecular weight forms, warfarin or other coumarin drugs, and fibrinolytics. In rare cases, surgery in the form of embolectomy or caval interruption or clot disruption by catheter may need to be considered.

### Acute pulmonary embolism

It is accepted that anticoagulants are effective in the treatment of acute pulmonary embolism. However, the only randomized trial to test this was small because it had to be abandoned on ethical grounds following the deaths, from necropsy-confirmed pulmonary embolism, of one-quarter of the patients in the placebo-treated group, a further 25% having clinical recurrence; there were no observed fatalities or recurrence in the heparinized group [151]. Additional evidence in support of the effectiveness of anticoagulants is provided by the observation that the frequency of recurrent thromboembolism is increased when the level of heparinization is subtherapeutic, according to clotting tests [152].

Acute massive pulmonary embolism is a familiar emergency to most doctors. The clinical diagnosis is usually supported by a normal chest film and an abnormal ECG, and leads to angiography. This procedure may sensibly be combined with attempts to dislodge or disrupt the clot by the catheter or guide wire [153]. This technique has been reported to produce haemodynamic improvement when successful. There have also been reports of removal of clot from pulmonary arteries by catheter and of the use of stents introduced by catheter to bypass the clot [154–156]. Supportive measures include the administration of oxygen and the use of plasma volume expanders; vasodilators are of course contraindicated. Deterioration in spite of the above procedures should lead to attempted embolectomy. If cardiac arrest occurs, vigorous cardiac massage should be continued and if possible the patient

put on cardiopulmonary bypass prior to embolectomy or catheter disruption.

In less urgent cases it is nevertheless important to act speedily as soon as the diagnosis is suspected. Anticoagulation with heparin, unless contraindicated, should be started immediately and the diagnostic strategy outlined above adopted. The various treatment options are discussed below.

### Heparinization

Initial anticoagulation with intravenous infractionated heparin has been the mainstay of treatment in pulmonary embolism. Heparin is a sulphated mucopolysaccharide obtained from animal lung and gut mucosa. It is available as a sodium or calcium salt and combines with the naturally occurring clotting factor activator antithrombin III, improving the inhibitory effect of this substance on factors IIa (thrombin) and Xa [157]. The efficacy of heparin is severely impaired if the level of circulating antithrombin III falls below 60% of the normal value [158], a point clearly relevant to subjects with thromboembolism resulting from a congenital deficiency of this thrombin inhibitor.

Heparin, in common with other anticoagulants, does not lyse clot and the object of therapy is to prevent extension or recurrence of thrombus while avoiding haemorrhagic complications, the principal determinant of which is the dose of heparin used [99,158]. The dosage of heparin is measured in international units according to a biological animal assay rather than by weight, and its clearance is unaffected by renal or liver disease.

A dose of 500–600 units/kg daily is recommended, the aim being to produce a plasma level of 0.3–0.4 units/mL, the concentration that has been shown experimentally to prevent thrombus formation [160]. For a 60-kg subject this would amount to 5000–6000 units every 4 h, giving a total daily dose of 30 000–36 000 units. With the availability of reliable intravenous pumps, it became standard practice to infuse heparin continuously once an initial bolus dose of 5000 units (10 000 units in severe cases) had been given. The infusion can be commenced at a rate of 1400 units/h but as the pharmacokinetics of heparin are very variable, so that it is exhausted more rapidly in the presence of extensive thrombus [161], it is advisable to use the higher end of the dosage range (1500 units/h) for patients in whom embolism is judged to be extensive. In cases of massive embolism or in the presence of a pre-existing thrombophilia the dosage may need to be increased to 60 000 units or more daily according to careful laboratory monitoring [162,163].

The activated partial thromboplastin time (APTT) is the most commonly used test for controlling anticoagulation with heparin and, in common with the thrombin time, requires a value 1.5–2.5 times the control figure [164,165]. It is usual practice to check the APTT 4–6 h after com-

mencement of treatment. If the APTT ratio is within the target range of 1.5–2.5 times the control, no change is made and the measurement is rechecked daily. Should the APTT rise above or fall below the desired range, the infusion rate is decreased or increased as the case may be, according to a validated nomogram; the use of which is more effective in achieving adequate heparinization quickly than intuitive prescribing by individual clinicians, resulting in inadequate anticoagulation [165–167]. An additional APTT estimation should be made 6–10h after any dose change. There is a circadian variation in heparin activity, which is at its peak during the night [168], so that blood should ideally be taken for routine APTT estimation at about the same time each day. A pre-existing thrombophilia should be suspected when the APTT response to heparin is poor.

Animal experiments purport to show that thrombus takes 7–10 days to become firmly adherent to a vessel wall [169], and it became routine practice to continue heparin for this length of time in humans [167]. It is now more usual to discontinue heparin after 5 days, provided that concurrent oral anticoagulation has become effective (see below).

Low molecular weight heparin is establishing a place in the management of thromboembolic disease [170–172]. Several different products are available, produced by enzymatic or chemical depolymerization of heparin to produce compounds of 4–6.5kDa. This chemical change makes for greater bioavailability, a longer half-life and greater reliability in terms of dose–response and reduction in bleeding complications. In particular, they do not bind in a non-specific way to plasma proteins, a fact that may explain some cases of apparent resistance to unfractionated heparin [173]. The drugs can be given subcutaneously once or twice daily without the need for monitoring of clotting times, and this makes them ideal for prophylaxis of venous thrombosis in high-risk patients and for outpatient treatment of deep venous thrombosis. Although not fully established as treatment for acute pulmonary embolism, studies of ‘submassive’ embolism, such as those requiring thrombolytic therapy, have suggested that in appropriate dosage they may be of similar efficacy to unfractionated heparin, so that their use is becoming accepted in uncomplicated cases [172,174]. The different low molecular weight preparations have different activities and dose regimens and cannot therefore be used interchangeably. In patients at greater risk of bleeding, unfractionated heparin infusion with laboratory control may be safer.

### Oral anticoagulation

By virtue of its long half-life (approximately 2 days), warfarin sodium was once thought to be better suited to poisoning rats than to treating patients but is now the most

commonly prescribed oral anticoagulant. It belongs to a group of coumarin derivatives whose anticoagulant properties were found to be the cause of bleeding in cattle fed on fermented sweet clover hay in the 1920s. It has a similar structure to fat-soluble vitamin K<sub>1</sub>, which it competitively inhibits, thereby blocking the production and activation of clotting factors II (prothrombin), VII, IX, X and other proteins involved in the coagulation process [175].

Warfarin does not act immediately, since the circulating clotting factors whose production it inhibits are not usually sufficiently cleared for 48h [176]. The usual practice is to start warfarin as soon as the diagnosis of venous thrombo-embolism is reasonably secure (often day 1) and to spread the loading doses over 3 days during which time heparin is continued until adequate oral anticoagulation can be shown to have been achieved by laboratory testing, a procedure made necessary as individual patients’ sensitivities to warfarin vary considerably [177,178]. Stability is commonly achieved by the third day of warfarinization at which point heparin may often be discontinued, the maintenance dose of warfarin being predicted by laboratory control on the fourth day (see below).

The most common coagulation test used in monitoring oral anticoagulant therapy is the one-stage Quick test [179] or a commercially available alternative. Blood is taken into a citrated tube (to remove calcium ions) and the laboratory adds a standard thromboplastin and an excess of calcium ions (as calcium chloride solution), measuring the time thrombus takes to form. As Quick thought that this test was a measure of prothrombin (factor II) activity only, the term ‘prothrombin time’ was introduced and remains acceptable by virtue of its widespread use, although the activity of factors VII and X are also measured. The prothrombin time is valueless unless related to a control time for the particular batch of reagent in use, the result being expressed as a ratio, i.e. patient’s prothrombin time/control’s prothrombin time. Attention has been paid to the characteristics of available thromboplastins, as there were fears that some commercially produced preparations might underestimate coumarin effect and lead to bleeding in the early stages of treatment, even though the prothrombin ratio was within the therapeutic range. In order to achieve reliable standardization in the UK, a batch of thromboplastin known as Manchester comparative reagent (MCR) was independently checked by the British Anticoagulation Panel and designated British comparative thromboplastin (BCT). This BCT was used to calibrate other thromboplastins, and prothrombin ratios so obtained were called the British corrected ratios (BCR). International standardization under the auspices of the World Health Organization has used a batch of BCT to establish an international normalized ratio (INR), and this system of reporting has been adopted in the UK and elsewhere.

INR control of warfarin induction has been shown to be

essential, as blind adherence to a regimen of 10 mg daily for 3 days may cause up to 30% of patients to be over-anticoagulated by the fourth day [177]. Adherence to the following steps should result in satisfactory induction of oral anticoagulation in a patient who is adequately heparinized:

- 1 check prothrombin time (INR) before first dose of warfarin;
- 2 if  $\text{INR} < 1.4$  give 10 mg warfarin as an evening dose;
- 3 repeat INR the following morning;
- 4 if  $\text{INR} < 1.8$  repeat 10 mg warfarin as an evening dose;
- 5 repeat INR the following morning;
- 6 if  $\text{INR} < 2.0$  repeat 10 mg warfarin as an evening dose.

The time of blood sampling (with the exception of step 1) and the time of dosing should be the same each day. When the INR is found to be higher at steps 2, 4 or 6, the next dose of warfarin should be reduced according to a predetermined schedule in order to avoid under-treatment or bleeding [181,182]. Prothrombin time (INR) is reliable even though heparin is being used, provided that the APTT or equivalent test is not above the therapeutic range of 1.5–2.5 times the control value. If the APTT is too high, the effect of heparin on the INR can be neutralized by adding protamine *in vitro* [183]. After the fourth dose of warfarin, the prothrombin time is rechecked at least weekly until a stable dose is achieved. Once heparin has been discontinued, follow-up control is achieved by the outpatient anticoagulant clinic, at first with weekly checks and then according to the stability of the measurement, with at least once-monthly checks for the duration of a limited course of treatment, or up to 3-monthly in the case of long-term therapy [180]. Caution should be exercised in the induction of oral anticoagulation as some patients are particularly sensitive to warfarin. These include the elderly and those with high risk factors such as congestive cardiac failure, liver disease and those on drug therapy known to potentiate warfarin. A loading dose of less than 10 mg daily is recommended under these circumstances [182].

The British Society for Haematology has recommended a target INR of 2.5 for treating deep venous thrombosis, pulmonary embolism and symptomatic inherited thrombophilia, and 3.5 in the management of a recurrence of either condition whilst on warfarin [182].

The duration of a course of oral anticoagulants is somewhat empirical. It is accepted that recurrence is likely if treatment is not continued on an outpatient basis after episodes of venous thromboembolism in hospital [39]. It has also been shown that continuation therapy with subcutaneous heparin in patients who have had proximal venous thromboses is ineffective when compared with oral anticoagulants over a similar 3-month period [184]. The British Thoracic Society has reported a controlled trial in which 4 weeks of anticoagulation was as effective as 3 months' treatment for postsurgical venous thromboembolism, but was less effective in medical patients [185].

Thus 4 weeks of warfarin can be recommended for the uncomplicated postoperative patient, while a 3-month course of anticoagulation has been generally acceptable for both deep venous thrombosis and pulmonary embolism arising *de novo* or in a medical patient. This remains an area of controversy and ongoing study, a recent placebo-controlled trial that extended oral anticoagulation with warfarin beyond 3 months for the first episode of idiopathic venous thrombo-embolism was discontinued after a mean period of 10 months with the conclusion that 3 months of treatment in these circumstances was inadequate [186]. The British Society of Haematology currently recommends 6 months of anticoagulation for pulmonary embolism and proximal deep venous thrombosis, 3 months for non-surgical calf vein thrombosis and 6 weeks for post-operative calf vein thrombosis, provided that there are no persistent risk factors [182]. When episodes have been life-threatening or when there has been recurrence, treatment may be for longer periods or even indefinitely in those with persistent risk factors or if no remediable cause has been identified. Particular care has to be taken with regard to drug interactions when warfarin is used [180].

### Thrombolytic therapy

Conventional therapy with heparin followed by oral anticoagulation is adequate treatment in the vast majority of patients with pulmonary embolism, historical evidence for this satisfactory response having been provided by follow-up with repeat lung scanning. This approach prevents the formation of new clot or the extension of existing thrombus and depends upon natural fibrinolysis to remove emboli from the lungs. Thrombolytic drugs stimulate the natural process by activating the plasminogen–plasmin system, which acts on preformed thrombus but may also induce a plasma proteolytic state that impairs blood coagulability and can cause serious haemorrhage. The original agents were streptokinase, derived from group C  $\beta$ -haemolytic streptococci [187], and urokinase, obtained from urine or from tissue culture of renal parenchymal cells [188]. Recently, more fibrin-specific drugs, such as alteplase (recombinant tissue plasminogen activator or rt-PA), anistreplase (acylated plasminogen–streptokinase activator complex) and single-chain urokinase, have been introduced.

Despite the theoretical attractions of thrombolytic drugs, they are used infrequently as a first line of treatment, in part because compared with heparin they have not been demonstrated to reduce early mortality [189,190] or improve long-term clinical results [191], and in part because of concern about the possibility of haemorrhagic side-effects. In spite of this, the original agents have been shown to accelerate improvement in pulmonary angiography and isotope lung scan, to reduce pulmonary artery pressure and to improve parameters of left and right ven-

tricular function in randomized controlled clinical trials that have compared up to 24 h of thrombolytic therapy with heparinization. Indeed the degree of lysis seen in patients treated with thrombolytics after 12–24 h was similar to that seen in the anticoagulated group at 1 week [190,192,193]. Similar results have been obtained with recombinant plasminogen activator, suggesting a potentially important role for these drugs in acute severe pulmonary embolism where there are signs of right ventricular strain and no likely bleeding points [194–196]. If they are used, peripheral intravenous infusion is adequate and there are no advantages to be gained from catheter infusion into the pulmonary artery direct.

There is no unanimity about patient selection for thrombolytic therapy, but it is reasonable to use these drugs in two categories of patient:

**1** those who are critically ill due to pulmonary artery obstruction and in whom further cardiopulmonary deterioration is judged to be lethal unless an invasive surgical procedure such as pulmonary embolectomy is carried out;

**2** patients judged to have had a large pulmonary embolus who are deteriorating clinically or failing to improve despite 24–48 h of treatment with heparin.

In support of this method of selection, trials have shown that patients with shock show a more impressive clinical response to thrombolytic drugs and that clinical deterioration is more likely in such patients when treated with heparin [190,192,193,197].

In order to avoid unnecessary risk, the diagnosis of pulmonary embolism should be established as firmly as possible before starting thrombolytic treatment. Ideally, this should include either an isotope lung scan that lends significant support or a positive pulmonary angiogram or spiral CT. Thrombolytic therapy is usually only used if the embolus is thought to have occurred within a week of the onset of treatment, as the drugs are relatively ineffective against old thrombus, possibly because the plasminogen content of the clot falls with time [189], although there is some evidence that activity may extend to 2 weeks [198]. The same contraindications apply to thrombolytic as to anticoagulants but absolute contraindications include active or recent haemorrhage and any known potential intracranial source of haemorrhage. There are clearly also increased risks of bleeding in peptic ulcer or other potentially haemorrhagic gastrointestinal tract disease and following surgery or parturition within the preceding 7 days. There are risks of haemorrhage to the fetus in pregnancy and also to patients with severe hypertension.

Both streptokinase and urokinase should be given by continuous infusion. For streptokinase, a loading dose of 250 000 units is given over 30 min followed by 100 000 units/h for up to 24 h [199]. Urokinase has been given at a dose of 4400 units/kg initially over 10 mins followed by the same dose hourly for 12–24 h. Increasingly, those with

experience of thrombolysis are using recombinant plasminogen activator (rt-PA) in a single intravenous dose of 100 mg over 2 h, and this appears as effective and no more dangerous in terms of haemorrhage than the older drug regimens [196]. The simplicity of this regimen suggests that it may become a standard treatment for severe embolic episodes. At the completion of the course heparin should be introduced, but not until the thrombin time has fallen to less than twice the baseline value. Heparin should be given at this stage by continuous infusion without an initial bolus, which could produce bleeding.

The risks of life-threatening bleeding during fibrinolytic therapy are not very different from those associated with heparin treatment, about 7% [34,200]. Persistent bleeding or oozing from venepuncture sites, cut-downs, arterial punctures, etc. may occur, and these procedures should be avoided wherever possible. Allergic reactions may occur to streptokinase and its acylated derivative in 15% of patients. Hydrocortisone may be given to diminish the chance of these. Fewer such reactions occur with urokinase and rt-PA.

### Supportive measures

Supportive measures consist of adequate analgesia, usually in the form of morphine or pethidine (which should of course not be given intramuscularly in anticoagulated patients). Oxygen therapy is provided according to arterial blood gas or  $\text{SaO}_2$  measurements and colloid infusion may be necessary to support left ventricular function in severe cases.

### Vena caval interruption

A number of procedures have been described by which the inferior vena cava is either totally or partially interrupted between the iliac and renal veins, in order to prevent emboli from the legs reaching the lungs. However, it has never been shown that any of these measures reduce mortality compared with standard heparinization followed by oral anticoagulation [200]. The need for vena caval interruption therefore requires critical examination before its clinical application. Fortunately death due to recurrent thromboembolism is extremely rare in patients who have completed an orthodox course of anticoagulant therapy [191] and this form of treatment is preferable to all others in the vast majority of patients.

Many different techniques are available, including complete ligation of the vena cava, suture plication, partial obstruction with metal clips and the positioning of various filters or umbrella devices designed to prevent large emboli passing across them [201]. The operative mortality of ligation, plication or clipping is in the region of 5–15% [202,203] compared with 1–3% for those filtering devices inserted under local anaesthesia and under radiographic control using a guide wire with a femoral or jugular vein

approach [203,204]. These procedures interfere with venous return and, unsurprisingly, one-third or more of patients with ligation experience chronic dependent oedema. Ultimately, filter devices may also occlude, with a rate of over 70% for the Mobin-Uddin umbrella and at least 5% for the various Greenfield filters [200,205]. Even with these potential prices to pay, the patient is not guaranteed freedom from further pulmonary emboli, as in about 5% of patients these may still occur either by the development of large collaterals or via the formation of thrombus on the cardiac side of the interruption [162,205]. Occasionally filters may themselves embolize or may perforate the wall of the vena cava [200].

In view of these various constraints, vena caval interruption is rarely justified but may be indicated in those few patients who:

- 1 experience life-threatening pulmonary emboli despite 'adequate' anticoagulation;
- 2 have a firm diagnosis of pulmonary embolism or extensive deep venous thrombosis but who cannot be treated with anticoagulants owing to some absolute contraindication.

### **Pulmonary embolectomy**

This operation was first carried out by Trendelenberg in 1908, although it was not until 20 years later that the first patient survived surgery with removal of an embolus [206]. In the most experienced hands, and with or without bypass, mortality rates are now around 20% [207–209], although it is likely that the risks in less experienced centres reflect those obtained in the 1970s, about 50% [210,211]. Such figures need to be treated with caution, since the surgeon who only carries out an occasional embolectomy is not only likely to be less skilled but also takes more persuading and therefore tends to operate on more desperate cases, while the more experienced surgeon tends to include less severely ill patients. Because of the very high risks involved, surgeons do not usually attempt pulmonary embolectomy without angiographic confirmation of the diagnosis; however, since most patients who die of massive pulmonary embolism do so within 30 min of the onset of symptoms [212], this group is unlikely to be helped by surgery but may benefit from the catheter techniques mentioned above (p. 736). Of those patients who survive long enough for the diagnosis to be confirmed, the mortality with medical treatment is low, even if more than half of the pulmonary circulation is shown to be obliterated [213].

It follows that pulmonary embolectomy is rarely indicated and seldom performed, even in centres with both experienced personnel and availability of bypass. Pulmonary embolectomy can be considered in the unusual case with firmly diagnosed massive embolism associated with severe hypotension, hypoxia and a deteriorating

situation [214] despite 'adequate' treatment with heparin or thrombolytic drugs.

### **Deep venous thrombosis**

The standard management of deep venous thrombosis has been admission of the patient to hospital for heparin infusion and initiation of oral anticoagulation using the regimens described above. The introduction of low molecular weight heparins has already altered this in many cases by allowing outpatient management. Several of the new heparins have now been shown to be as effective as the standard regimen when given as a fixed subcutaneous daily or twice-daily dose [215–218]. At present it would be appropriate to treat a patient with uncomplicated venous thrombosis with a low molecular weight heparin for 5 days and to introduce an oral anticoagulant in the normal way as described above. In the future, it may prove possible to substitute longer-term low molecular weight heparin for warfarin for a more prolonged period. This has not yet been tested in a controlled trial and would carry the risk of thrombocytopenia.

### **Prophylaxis**

The consequences of venous thrombosis and embolism are so serious, both in individual morbidity and mortality and in costs to the health services, that routine prophylaxis has now become mandatory in the hospital setting [219–221]. The risks to the individual include the dramatic consequence of fatal pulmonary embolism and the less dramatic but very troublesome postphlebotic leg syndrome and venous ulceration. Prophylaxis involves making a risk assessment in individual patients and applying a locally agreed protocol of management depending on the results of the assessment.

### **Individual risk assessment**

Two factors contribute to risk of venous thromboembolism: personal predisposition and acute illness or injury (Table 25.2). Those at highest risk are people having major orthopaedic surgery, especially of the hip, pelvis or leg, or abdominal surgery for cancer and those with stroke involving a leg or paraplegia. Others with serious illness, major trauma or surgery who give a history of previous thromboembolic disease or of a thrombophilia should also be regarded as at highest risk. Such patients have been shown to have risks of venous thrombosis and fatal pulmonary embolism of around 50% and up to 10%, respectively. Major acute medical illness, such as myocardial infarct or heart failure, and major trauma constitute a moderate risk in the absence of predisposing factors, as does less severe trauma or surgery in the presence of predisposing factors. All other patients are regarded as at low risk.

**Table 25.2** Risk factors for venous thromboembolism.

---

<i>Predisposing factors</i>
Increasing age
Obesity
Over 4 days in bed
Pregnancy and puerperium
Oestrogens (50 µg + daily)
Previous deep venous thrombosis or embolism
Thrombophilic disease
Homocystinaemia
 <i>Illness/injury</i>
Major trauma or surgery
Pelvic and abdominal cancer
Cardiac failure
Recent myocardial infarct
Leg paralysis
Severe infection
Polycythaemia
Paraproteinaemia
Nephrotic syndrome
Inflammatory bowel disease
Behçet's disease
Paroxysmal nocturnal haemoglobinaemia

---

## Methods of prophylaxis

### Mechanical measures

Graduated elastic compression stockings have been shown to be effective in prevention of venous thrombosis postoperatively, and in one major meta-analysis appear to be as effective as low-dose heparin in reducing risks of pulmonary embolism after hip replacement [222,223]. Other mechanical devices that intermittently compress the legs are also widely used and probably equally effective. Leg compression has the advantages of not increasing risk of bleeding, except possibly after prostate surgery, and being suitable for all patients save those at risk of ischaemic leg complications. It is commonly combined with pharmacological measures.

### Low-dose heparin

Double-blind prospective randomized trials involving over 4000 patients have shown that low-dose unfractionated heparin is effective in reducing the incidence of deep venous thrombosis and fatal pulmonary embolism in patients over the age of 40 years undergoing abdominal, thoracic and pelvic surgery under general anaesthesia [224,225]. The recommended dose is 5000 units subcutaneously 2 h before the procedure, to be continued every 12 h until the patient is ambulant. Monitoring of clotting times is not necessary. An 8-hourly regimen may also be used but probably confers no additional benefit for a greater likelihood of bleeding [226]. An even smaller dose of heparin (1 unit/kg/h) has been used as a continuous

infusion, although this 'ultra-low dose regimen' never gained wide acceptance [227].

These small doses of heparin augment a naturally occurring factor X inhibitor [228] and, while they cannot be guaranteed to prevent thromboembolism, the reductions are highly significant, from approximately 25% to 7% for deep venous thrombosis and from 6% to less than 1% for pulmonary emboli [229]. These figures argue strongly for the widespread use of subcutaneous heparin, and it was estimated that 4000–8000 deaths per annum could be avoided in the USA by its routine prescription in these groups of patients [230,231]. Low-dose heparinization may be complicated by wound or intra-abdominal haematomas [224,232] but these are not usually of a serious nature [233] and there is a much lower risk of haemorrhage than with full anticoagulation. There is also a risk of thrombocytopenia, which occurs in 3–4% of patients on prophylactic heparin, sufficiently frequently for it to be necessary to monitor platelet counts in these patients. Low-dose heparinization is contraindicated in patients with a bleeding tendency or in those neurosurgical patients in whom postoperative bleeding could be disastrous.

Although the value of low-dose heparin at conventional doses in patients following abdominal, thoracic and pelvic surgery is undisputed, its efficacy in other at-risk groups is not established and remains a subject of controversy. One such high-risk group in which a convincing case cannot be made for low-dose heparin is that comprising patients who have had major orthopaedic surgery or suffered trauma associated with a high incidence of venous thrombus formation. Thus most series have shown that low-dose unfractionated, as opposed to low molecular weight heparin prophylaxis is ineffective in patients following total hip or knee replacements [67]. Because of the lack of clear benefit and because of conflicting data, this form of prophylactic therapy has not been widely used in these groups, particularly as it carries the risk of wound haematoma that might jeopardize the success of the surgical procedure [233].

Myocardial infarction is another risk group in which the beneficial effect of low-dose heparin is indeterminate, although the use of full, short-term anticoagulation appears to reduce the frequency of thromboembolic complications [234,235]; overall mortality has not been shown to be reduced unless the data from different trials are pooled [236]. Data regarding the efficacy of subcutaneous heparin in patients after myocardial infarction are conflicting [237].

Patients undergoing major urological surgery, including suprapubic prostatectomy and cystectomy, are inadequately protected by subcutaneous heparin [238], whereas this form of treatment is effective in transurethral prostatectomy [239]. The success of subcutaneous heparin in many groups of surgical patients has led to its more widespread

use in patients immobilized through medical illness, such as congestive cardiac failure and strokes [240].

### Low molecular weight heparins

These agents, and the heparinoid danaparoid, are also given by subcutaneous injection on a once- or twice-daily basis, without the need to monitor clotting times, although platelet counts do need to be measured as with standard heparin. They have been shown to be more effective in orthopaedic surgery and also to have some advantage in general surgical operations [241–243].

### Oral anticoagulants

The main use of oral anticoagulation has been in hip surgery, where these drugs have been shown to be effective. However, they have the disadvantage of the need for careful control of prothrombin time. It is usual to start therapy either with a low dose before surgery or with the full dose after surgery to reduce the risk of bleeding. A number of trials has shown low molecular weight heparin to be as effective as warfarin in hip surgery [243].

### Dextran 70

The plasma expander dextran has antithrombotic effects, both as a result of its haemodiluting effect and also because of a specific effect on platelet adhesiveness and fibrin formation [244]. It has been claimed that it has an equivalent prophylactic effect to warfarin if given before, during and in the early postoperative phase after elective hip surgery [245]. It is infused slowly over a period of about 24 h. Haemorrhagic complications are less common with this treatment but allergic reactions and volume overload are potential problems. Dextran may also interfere with blood cross-matching and biochemical estimations and can cause renal failure if given in the presence of dehydration. It is not normally used in those groups known to benefit from low-dose unfractionated heparin for, although it may be as effective [246], it is expensive and less safe to administer. Although it is effective following elective hip surgery, it is less than low molecular weight heparin [243].

### Aspirin

Aspirin inhibits thromboxane  $A_2$  and also reduces platelet adhesiveness, but unfortunately its efficacy as a venous thromboembolic prophylactic in the postoperative state was not demonstrated in a British Medical Research Council trial [247]. The reader should not be surprised to learn that some workers have found aspirin to be of limited effectiveness following total hip replacement [248], while others have not [249], and there is insufficient evidence to commend it for general use as a venous antithrombotic agent.

### Other agents

Conflicting claims have been made for many other drugs when used either alone or in combination. These include other prostaglandin inhibitors, such as sulfinpyrazone (sulphinpyrazone) and oxyphenbutazone, the antimalarial hydroxychloroquine, dipyridamole and drugs thought to enhance fibrinolysis, such as anabolic steroids and phenformin. The efficacy of all these agents is unproven.

### A preventive protocol

All patients at high or moderate risk should be given specific prophylaxis, while patients at low risk (Table 25.1) should only be subject to general measures to ensure early mobilization and leg muscle activity [219–221].

#### Patients at high risk

As with all hospital patients, those at high risk should be mobilized early and encouraged to do leg exercises. In addition they should receive specific prophylaxis. Patients having hip surgery should receive low molecular weight heparin (or heparinoid) or warfarin (adjusting the dose postoperatively to an INR of 2–3). Dextran 70 is a somewhat less secure option. In the case of patients at risk of bleeding, intermittent leg compression or graduated stockings are reasonably effective. Patients with hip or major leg fracture should be treated similarly, though here low molecular weight heparin appears to be the best option in terms of efficacy. In knee and major abdominal surgery, prophylactic heparin and leg compression should be combined, as they should in stroke and other conditions causing leg paralysis after intracranial haemorrhage has been excluded.

#### Patients at moderate risk

Patients over the age of 40 undergoing major surgery and with any of the risk factors in Table 25.2 should be given subcutaneous heparin, either low dose unfractionated or low molecular weight, or leg compression if they have a risk of bleeding. In medical patients immobile due to severe illness, low-dose heparin or adjusted-dose warfarin (INR 2–2.5) are recommended. Leg compression is suitable for those at risk of bleeding and who do not have ischaemic limbs, and may be combined with anticoagulation. In patients with myocardial infarction, aspirin and thrombolytic drugs are now used routinely, and full anticoagulation is sometimes indicated by complications such as mural thrombosis and atrial fibrillation. In other circumstances, if the patient remains immobile, prophylaxis with low-dose heparin or adjusted-dose warfarin should be considered. In neurosurgery and often in major trauma, anticoagulation is contraindicated and leg compression is essential.

### Management in pregnancy and the puerperium

The management of deep venous thrombosis or pulmonary embolism in pregnancy is constrained by considerations with regard to the developing fetus. First, in achieving a diagnosis it is desirable to expose the fetus to as little ionizing radiation as possible. Both compression ultrasound and impedance plethysmography are acceptable options for deep venous thrombosis and an isotope perfusion scan, followed if need be by a ventilation scan which is the investigation of choice for pulmonary embolism as the very low radiation dose poses a negligible risk to the fetus [250]. Conventional chest radiography and ascending venography are permissible with pelvic shielding although this may compromise visualization of the pelvic veins. Secondly, treatment requires a drug that is effective in preventing further thrombosis without harming the fetus or causing the mother to bleed excessively at parturition.

Coumarin compounds such as warfarin cross the placental barrier and are potentially teratogenic in the first trimester, being associated with multiple congenital abnormalities including chondrodysplasia punctata. Although there are those who believe that warfarin may be safely used with careful clotting control in the second and third trimesters, with discontinuance at 36 weeks, this policy is not recommended because of reports of neurological defects and because of the risk of fetal or maternal haemorrhage in the case of premature labour [43]. Warfarin may be taken by breast-feeding mothers without risk to the child [251].

Unfractionated heparin does not cross the placenta and is not teratogenic. It is the treatment of choice for both deep venous thrombosis and pulmonary embolism in pregnancy and should be given intravenously initially for 1–2 weeks at standard dosage with usual clotting control [251]. It is impracticable to continue it intravenously throughout pregnancy, and indeed this carries the risk of osteoporosis and thrombocytopenia. It can, however, be given subcutaneously at a dose of 5000 units either every 12h and can be self-administered satisfactorily in most cases [251] with laboratory APTT control, being replaced with intravenous heparin before elective induction, this being discontinued 6h before expected delivery with recommencement and conversion to warfarin on the first post-partum day [252]. This treatment can be continued after birth for up to 6 months. Low molecular weight

heparin is probably safe in pregnancy but there is currently insufficient data relating to efficacy in this condition so that its routine use cannot yet be endorsed [252].

In terms of prophylaxis, women who have had a previous episode, those with acquired thrombophilia (lupus or anticardiolipin antibodies) and those with other risk factors, such as pre-eclampsia, surgery or serious medical disease, should have subcutaneous heparin after delivery and standard warfarin therapy for 6–12 weeks. In the case of those with a previous history, antenatal prophylaxis with subcutaneous heparin or graduated stockings should be considered. If there is a known genetic thrombophilic disorder, antenatal and postnatal subcutaneous heparin are normally necessary and the advice of a specialized unit should be sought.

### Prognosis

The long-term prognosis of patients who survive episodes of acute pulmonary embolism is good, provided that there is no serious coexisting cardiopulmonary or malignant disease to influence the outcome. The overall mortality in subjects free of heart failure prior to the embolic episode is 8–9% [191,213], whereas in those with preceding heart failure it is five to eight times higher. In keeping with this, between two-thirds and three-quarters of lung perfusion scans show resolution within 1 year of diagnosis [192,252]. Sutton and colleagues [191,253] considered the prognosis of pulmonary embolism in four clinical categories:

- 1 acute massive, in which more than 50% of the pulmonary circulation is lost, with a very short history of less than 4h and with an acute episode of cardiovascular collapse;
- 2 subacute massive, in which also more than 50% of the pulmonary circulation is lost but with a longer history exceeding 2 weeks and with no episodes of acute collapse;
- 3 acute minor, in which less than 50% of the pulmonary circulation is lost but with a relatively short history of less than 2 weeks;
- 4 chronic, with a long history of months or years and with a pulmonary angiogram showing diminished pulmonary perfusion with irregular pulmonary vessels.

They found that the late prognosis for the first three groups was good, with no chronic pulmonary hypertension and cor pulmonale, but that 'chronic pulmonary embolism' (the smallest group) followed a progressively worsening course with right heart failure and eventual death.

# PULMONARY HYPERTENSION

ANTHONY SEATON

## Physiological considerations

### Mechanics of the pulmonary circulation

The pressure in the pulmonary artery is determined primarily by left atrial pressure, the resistance to flow offered by the pulmonary vessels and the flow of blood through the pulmonary circulation. The proximal pulmonary arteries are of relatively high compliance and this is the main factor determining the low systolic pressure in the system. The diastolic pressure is determined by the resistance offered by the muscular precapillary vessels, and again in normal circumstances this is low. These relationships may be summarized by the simple formula:

$$P_{pa} = P_{la} + (\dot{Q}_p \times PVR) \quad [26.1]$$

where  $P_{pa}$  is the mean pulmonary arterial pressure,  $P_{la}$  the mean left atrial pressure,  $\dot{Q}_p$  the pulmonary blood flow and  $PVR$  the pulmonary vascular resistance. Of these, pulmonary arterial and left atrial pressures may be measured directly using cardiac catheterization. In many instances, a clinically acceptable estimate of left atrial pressure may be obtained by wedging a catheter in a small pulmonary artery rather than by the somewhat more complex method of atrial septal puncture. The blood flow through the pulmonary vessels may be calculated using the Fick principle as applied to the transport of oxygen by the blood [1]. If the uptake of oxygen ( $\dot{V}O_2$  in mL/min) can be measured, conventionally over 3 min with the use of an air-filled spirometer and carbon dioxide absorber, and the oxygen content (in mL/dL) of systemic arterial ( $CaO_2$ ) and mixed venous ( $C\bar{v}O_2$ ) blood determined, then blood flow is given by the equation:

$$\dot{Q}_p = \frac{\dot{V}O_2}{CaO_2 - C\bar{v}O_2} \times \frac{1}{10} \text{ (L/min)} \quad [26.2]$$

This simply states that during a period of 1 min a given volume of blood flowing through the pulmonary capillaries absorbs the amount of oxygen consumed and that this is the same amount as the difference between the con-

centration of oxygen in the main pulmonary artery and that in the left side of the heart. Clearly, an accurate measurement assumes steady flow conditions and no changes in oxygen consumption during the period of sampling. Nevertheless, it provides a figure that is of clinical value and which can be used with the pressure measurements to calculate PVR:

$$PVR = \frac{P_{pa} - P_{la}}{\dot{Q}_p} \quad [26.3]$$

The normal PVR is less than 2 mmHg/L/min, in contrast to the systemic resistance of 10–20 mmHg/L/min.

This traditional method of measuring cardiac output has now largely been supplanted by the somewhat less cumbersome method of thermodilution [2], a technique involving injection of 10 mL cooled dextrose solution into the right atrium via a cardiac catheter with a thermistor at its tip positioned in the pulmonary artery. The fall in temperature is sensed as a rise in resistance and a computer integrates the change against time to give a reading of output. Other methods of measuring cardiac output that have now fallen into disuse because of their complexity include dilution of injected dye or a relatively insoluble radioactive isotope such as krypton [3,4] and the rate of uptake of nitrous oxide while inside a plethysmograph [5].

The normal pulmonary artery pressure at rest is around 25/10 mmHg, with a mean of about 15 mmHg. During exercise, cardiac output increases and there is a roughly proportionate rise in pulmonary arterial pressure initially, followed by a plateau for about 7 min and then a fall to resting levels accompanied by a drop in vascular resistance [6,7]. The normal pulmonary blood flow at rest is about 4 L/min/m<sup>2</sup> and this can double during exercise [7]. Pregnancy increases cardiac output until the last trimester but is associated with a normal or low pulmonary artery pressure [8].

### Regulation of pulmonary vascular tone

The pulmonary vascular endothelial cell is central to the

control of tone in the pulmonary circulation, and recent advances in the understanding of this have important implications in the management of patients with pulmonary hypertension. The endothelium comprises active secretory cells that produce both vasodilator and vasoconstrictor substances [9,10]. Nitric oxide (previously known as endothelium-derived relaxing factor), prostacyclin and endothelium-derived hyperpolarizing factor are vasodilators, while endothelin 1 is the main vasoconstrictor. There is interaction between these two systems, with endothelin 1 promoting release of nitric oxide and conversely nitric oxide inhibiting production of endothelin 1, although the evidence suggests that PVR is normally kept low by active nitric oxide and prostacyclin secretion with smooth muscle relaxation and thus vasodilatation. Hypoxia appears to be a factor in both inhibiting release of nitric oxide and causing release of endothelin 1. In normal circumstances endothelin 1 seems to be removed by the pulmonary circulation, since arterial levels are lower than venous [11], but plasma concentrations rise in response to hypoxia [12]. In addition, hypoxia has been shown to close potassium channels in the membrane of pulmonary vascular smooth muscle cells, leading to depolarization, calcium influx and vasoconstriction [13,14].

Nitric oxide acts primarily by stimulating a rise in cyclic GMP in the smooth muscle cell via its action on guanylate cyclase. This results in the activation of potassium channels in the cell membrane, causing a rise in intracellular potassium, a corresponding fall in calcium, and muscular relaxation. Prostacyclin acts on adenylate cyclase to increase cyclic AMP, also decreasing calcium levels, while endothelium-derived hyperpolarizing factor acts directly on the potassium channels. Conversely, endothelin 1 acts on specific smooth muscle receptors, activating protein kinase C and leading to opening of calcium channels with a rise in intracellular calcium and muscle contraction.

This outline of the normal control of PVR provides a framework for understanding the mechanisms of pulmonary hypertension, especially if this syndrome starts with either extrinsic or intrinsic impairment of endothelial function and leads to muscular constriction and hypertrophy/hyperplasia with secondary changes in the media and development of abnormal vascular channels. While it therefore provides a possible unifying concept of the aetiology of several types of pulmonary hypertension, in many cases it does not explain the primary aetiological events that might lead to the activation or inhibition of the control mechanisms, and this remains an area of active research.

## Causes of pulmonary hypertension

From the foregoing, it can be seen that physiological rises in pulmonary arterial pressure accompany exercise.

However, a persistently raised pressure may result from a rise in pulmonary venous/left atrial pressure, an increase in PVR or an increase in the flow rate through the pulmonary vessels. As may be inferred from the changes that occur during exercise and in pregnancy, a high flow rate is not necessarily associated with pulmonary hypertension because the pulmonary vascular bed is able to increase its capacity, via recruitment of previously unperfused capillaries, and therefore lower its resistance to increased flow. The considerable spare capacity of the lung's vascular bed can be seen from the results of experiments on dogs, where removal of some 75% of the capillary bed is required to cause a doubling of pressure; this augmentation gradually reduces in the following years [15]. Nevertheless, this simple concept of the mechanisms of pulmonary hypertension allows a classification of its causes that is convenient for clinical differential diagnosis.

The important causes of pulmonary hypertension are shown in Table 26.1. It should be appreciated that pulmonary vascular obstruction is a common feature of prolonged pulmonary hypertension of all causes, although the pathological and clinical features of the diseases may differ considerably.

**Table 26.1** Causes of pulmonary hypertension.

---

### *Increased pulmonary vascular resistance*

#### *Hypoxic*

- Chronic airflow obstruction
- Restrictive lung diseases
- High altitude
- Hypoventilation syndromes

#### *Obstructive*

- Primary pulmonary hypertension
- Drug-induced and dietary causes
- Collagen diseases
- Hepatic cirrhosis
- Thromboembolism
- Tumour embolism
- Schistosomiasis, tropical eosinophilia
- Sickle cell and thalassaemia disease
- Veno-occlusive disease
- Myeloproliferative disorders
- Human immunodeficiency virus infection

### *Increased pulmonary venous pressure*

- Mitral valve disease
- Left ventricular failure
- Cor triatriatum
- Left atrial myxoma
- Dilated cardiomyopathy
- Hilar fibrosis

### *Increased pulmonary blood flow*

- Atrial septal defect
  - Ventricular septal defect
  - Patent ductus arteriosus
-

### Increased pulmonary vascular resistance

This group includes all the conditions of primary interest to the respiratory physician. Increased vascular resistance may occur initially as a response to chronic hypoxia, for example people who live at very high altitude or patients with chronic airflow obstruction, or as a result of blockage of pulmonary vessels due to either intramural changes or intraluminal disease. Examples of the latter are embolism by blood clot, tumour or *Schistosoma* ova, while the former is seen in drug-induced and idiopathic pulmonary hypertension and in veno-occlusive disease.

### Hypoxic pulmonary hypertension

#### *Cor pulmonale*

##### *Clinical features*

This condition is discussed in Chapter 24. It occurs characteristically in the patient with severe prolonged irreversible airflow obstruction who presents with breathlessness and episodes of congestive cardiac failure, but may also be seen in extensive bronchiectasis, cystic fibrosis and restrictive lung diseases. The clinical signs, apart from those of the lung disease, include an atrial gallop rhythm, best heard in the epigastrium, and elevation of the *a* wave of the jugular pulse. Atrial fibrillation is not uncommon and a third heart sound heralds the onset of right ventricular failure. Tricuspid regurgitation, with giant *v* waves in the jugular pulse and pulsatile liver, is a late manifestation. Signs of cardiac enlargement are often absent because of the overinflated lungs.

The arterial blood gases show hypoxaemia and a compensated respiratory acidosis; polycythaemia is frequently present. The ECG shows tall, vertically oriented P waves, a vertical or rightwards-pointing frontal QRS axis and persistence of an S wave round to  $V_5$  or  $V_6$  [16,17] (Fig. 26.1). It is unusual to see a dominant R wave in  $V_1$  in this condition. T waves are often inverted in the anterior chest leads. The important radiographic sign is widening of the pulmonary hilum and enlargement of the main pulmonary arteries [18,19]. Although measurement of the transverse diameter of the descending branch of the right pulmonary artery at its widest point is not a reliable guide to the absolute level of the pulmonary pressure, if it is greater than 20 mm pulmonary hypertension is likely to be present (Fig. 26.2). Transoesophageal echocardiography may demonstrate the relative thickness of right and left ventricular walls and the presence and amount of tricuspid regurgitation and, subject to a tendency to underestimation, may be used to calculate pulmonary arterial pressure [20–22].

**Fig. 26.1** ECG of patient with cor pulmonale showing tall peaked P waves in leads II and III, right axis deviation and S waves round to  $V_6$ .

##### *Pathology*

The right ventricular wall is hypertrophied and may even be as thick as that of the left ventricle [23]. Dissected free of the left ventricle and septum, the right ventricle is considered to exhibit hypertrophy if it weighs more than 80 g and if the ratio of the left to right ventricular weights is less than 2:1 [24]. The main pulmonary artery is dilated, often to an appreciably greater diameter than that of the aorta, and its wall may be thicker than that of the aorta [25]. Fatty streaking or atheroma may be seen in the intima. Microscopically, the main pulmonary artery shows much increased elastic tissue of the acquired type, i.e. the fibres are irregular in width and separated by wider spaces than those of the aorta [26]. The elastic pulmonary arteries (those vessels down to about 1 mm diameter) may show atheroma, medial thickening and dilatation, but the main changes occur in the pulmonary arterioles [27]. Slight medial muscular hypertrophy may occur in the smaller muscular pulmonary arteries, although they and the arterioles show the development of longitudinal muscle in the intima. Intimal fibrosis also occurs and the pulmonary arterioles develop a muscularized media between two elastic laminae. In any condition involving loss of alveolar surface area, be it emphysema or fibrosis, the capillary bed is reduced, and if this is extensive it may contribute towards the development of pulmonary hypertension [28,29].

In patients with extensive bronchiectasis or with cystic fibrosis, a prominent feature is a much increased bronchial circulation, reflected pathologically by dilated bronchial arteries and anastomoses between them and pulmonary arteries [30,31]. These vessels may make an important contribution to pulmonary hypertension, carrying blood at systemic pressures.

Pulmonary fibroses leading to honeycomb change are

**Fig. 26.2** Chest radiograph of patient with cor pulmonale showing marked enlargement of proximal pulmonary arteries.

associated with somewhat different alterations in the pulmonary arterial tree. Here there is marked intimal fibrosis and generalized medial hypertrophy of muscular pulmonary arteries, with ultimate fibrous obliteration [32,33]. In some cases, the development of thin-walled anastomatic vessels [34] may reduce the vascular resistance and thus prevent the development of pulmonary hypertension but, at the same time, increasing hypoxaemia by allowing shunting of blood across unventilated lung.

### *High-altitude disease*

#### *Clinical features*

As discussed in Chapter 2, residence at high altitude is associated with chronic hypoxaemia. Interesting differences have been described between the native people of the high Andes, whose ancestors have lived at 4000 m for tens of thousands of years, those residents of the Colorado Rockies whose ancestors have lived at over 3000 m for a century at most, and people who were born at sea level but have moved to high altitude [35]. The first group, the Quechua Indians of Peru, have relatively mild pulmonary hypertension, usually without adverse physiological effects [36], although a few develop Monge's disease [37,38]. The residents of Leadville, Colorado, tend to develop more severe pulmonary hypertension leading to

right-sided heart failure, often in childhood [39]. People moving to high altitude are at risk of acute pulmonary hypertension and pulmonary oedema (see Chapters 2 & 27).

Monge's disease occurs in the native people of the high Andes and is characterized by increasing cyanosis, hypoventilation, polycythaemia, finger clubbing, nail haemorrhages and severe pulmonary hypertension leading to cardiac failure. These changes are reversible and the disease remits if the patient is removed to lower altitudes, only to recur if he or she returns. It is not known why some individuals develop Monge's disease while most of those exposed to the same ambient oxygen tensions do not. The patient's age and altitude of residence may play a part, although the primary physiological abnormality appears to be loss of the adaptive altitude hyperventilation with insensitivity of the ventilatory response to carbon dioxide [40]. It may be that those who develop disease simply represent the extreme, least effective end of a spectrum of adaptation to hypoxia. In this respect, it is interesting to note that when chronic airflow obstruction occurs in people born and raised at high altitude the associated rise in pulmonary arterial pressure seems to be less than would occur at sea level for the level of hypoxaemia, indicating that the peripheral vascular bed itself becomes less sensitive to hypoxic stimuli in such people [41].

Studies of the comparative pathology of humans and animals living at high altitude and sea level have shed light on these adaptive changes [42]. Those animals, such as the llama, certain rodents and the yak, that have lived for millenia at high altitude in the Andes or Himalayas have a relatively low-resistance pulmonary circulation, with minimal muscularization of muscular pulmonary arteries; in contrast, native humans at these altitudes develop mild pulmonary hypertension and pronounced muscularization of these arteries. In the case of high-altitude animals, it appears that genetic *resistance* to pulmonary hypertension, expressed in morphological terms by absence of changes in pulmonary vessels, has developed, whereas in the indigenous humans a natural *acclimatization* has developed that is not always complete. Interesting cross-breeding experiments between high-altitude yaks and their low-altitude cousins (domestic cattle) have shown that resistance to hypoxic vascular change appears to be inherited as an autosomal dominant. Readers of this chapter who play Scrabble might like to know that the offspring of a yak and a cow is called a dzo, while that of a dzo and a bull is a stol!

### Pathology

The pulmonary vessels of dwellers at high altitude show the characteristic changes associated with prolonged hypoxia, namely muscularization of the pulmonary arterioles, with development of a distinct media, and the appearance of longitudinal intimal muscle. Proliferative changes are not a feature, in keeping with its potentially reversible nature.

### Alveolar hypoventilation

There are several clinical syndromes in which chronic alveolar hypoventilation occurs, leading to hypoxaemia, hypercapnia, polycythaemia and pulmonary hypertension (Table 26.2). Acute alveolar hypoventilation may occur after certain brain injuries and in intoxication with narcotic drugs. All the chronic forms may culminate in pulmonary hypertension, characterized pathologically by muscularization of the pulmonary arterioles, as in high-altitude disease.

### Mechanisms of hypoxic pulmonary hypertension

Teleologically, it is reasonable to postulate that constriction of small pulmonary vessels may occur as a response to alveolar hypoxia in order to preserve an appropriate balance between ventilation and perfusion in the lung. The presence of similar pathological changes involving the smallest precapillary vessels in a wide variety of conditions associated with alveolar hypoventilation, and their absence in patients with congenital cyanotic heart

**Table 26.2** Causes of chronic alveolar hypoventilation.

disease in whom the pulmonary circulation is protected from high flows by pulmonary stenosis, suggest that alveolar rather than mixed venous hypoxia is the initial stimulus. It is likely that hypoxia acts directly on pulmonary vessels, alveolar gas being able to diffuse to vessels of arteriolar size quite rapidly [43,44]. The evidence discussed above suggests that a fall in alveolar  $PO_2$  to below about 10 kPa (75 mmHg) is sensed by pulmonary smooth muscle both directly by its effect on potassium channels and indirectly by the influence of mediators released from endothelial cells, increase in endothelin 1 and decrease in nitric oxide both causing vascular constriction [45]. Such a mechanism acts by increasing calcium flux across the cell membrane, and it has been shown that inhibition of calcium influx reduces hypoxic vasoconstriction [46,47].

### Obstructive pulmonary hypertension

#### Primary pulmonary hypertension

##### Clinical features

Pulmonary hypertension of unknown cause may occur at any age, although there is an excess among female patients in the reproductive years so that the condition is seen more frequently in young women than young men. It is a rare condition, occurring in 1–2 per million per annum, reflected in the literature by the fact that specialized university hospitals have been able to report studies of only

three to five patients per year [48,49]. A familial type is recognized, being inherited as either an autosomal dominant or recessive, though this may be missed if careful investigations of the family history are not made [50,51]. In some studies an association with the major histocompatibility types HLA-DR3, DRw52 and DQw2 has been noted [52]. An association with autoimmune disease has also been suggested, since patients often seem to have Raynaud's syndrome and positive tests for autoantibodies [53]. There is also an association between systemic lupus erythematosus and pulmonary hypertension, although in this disease the pulmonary vascular involvement is usually mild [54,55]. In contrast, in hepatic cirrhosis a severe form of plexogenic pulmonary hypertension may occur, albeit rarely [56,57]; even more rarely the syndrome has been described in biliary cirrhosis, chronic active hepatitis and portal hypertension without cirrhosis [58,59]. There has been at least one report of regression after liver transplantation [60].

The patient usually presents at a stage when symptoms have occurred, and by this time the disease is well advanced in pathophysiological terms. The presenting symptoms are most commonly steadily increasing exertional dyspnoea, fatigue, chest pain of an anginal type, palpitations, dizziness on effort, and syncope [61]. Occasionally patients complain of ankle swelling. In a proportion of patients, in some series as many as 30%, there may be a history of Raynaud's syndrome [48,62]. As mentioned above, some others may have evidence of chronic liver disease, usually cirrhosis. The physical signs are characteristic: there is evidence of right ventricular enlargement with a left parasternal lift and tapping apex beat, together with a loud and often single second heart sound, a systolic ejection click, a fourth heart sound, a Graham Steell left parasternal diastolic murmur and elevated jugular *a* waves [63,64]. Recent studies suggest that the latter is in fact a summation of *a* and *v* waves [65]. In the absence of evidence of other primary heart or lung disease or of thromboembolic episodes, these signs allow the diagnosis to be made with confidence. It may be confirmed by ECG, which shows P pulmonale and signs of right ventricular hypertrophy (in this disease, a dominant R wave in  $V_1$  and  $V_2$  is characteristic; Fig. 26.3), and chest radiography, which shows large proximal pulmonary arteries and relatively avascular lungs (Fig. 26.4). A lung scan shows uniform distribution of perfusion even when the macroaggregates are injected with the patient in a sitting position (as opposed to the normal hypoperfusion of the upper zones in this circumstance). The characteristic moth-eaten appearance of the scan in multiple thromboembolic disease is absent.

Final confirmation of the diagnosis may require cardiac catheterization and sometimes lung biopsy. Both procedures are risky, deaths occurring during catheterization even in the absence of injection of hypertonic radiological

Fig. 26.3 ECG of patient with primary pulmonary hypertension showing P pulmonale, right axis deviation, dominant R wave in  $V_1$  and persistent S wave in  $V_6$ . Unusually, T waves remain positive in precordial leads in this patient.

contrast medium [48,66]. The potential benefits of these procedures should therefore be considered seriously before embarking on them, and in some cases it will be decided that they are not justified. The reason for performing them should be to exclude other, more readily treatable conditions or as a preliminary to a trial of treatment, in order to assess potential to respond.

The physiological abnormalities associated with primary pulmonary hypertension are non-specific [67,68]. Lung volumes and ventilatory capacity are usually close to normal, although a restrictive pattern may be seen. Diffusing capacity is characteristically reduced and does not rise on exercise. Arterial oxygen desaturation and hypocapnia are present and  $Pao_2$  falls further on exercise. This hypoxaemia is related to intrapulmonary shunting. The pulmonary arterial pressure and vascular resistance are of course much raised, but wedge pressure, if recordable, is normal.

While it is likely that primary pulmonary hypertension will be shown to include several distinct diseases, as with many clinical syndromes of unknown aetiology, until these have been separated it is useful to consider it a diagnosis of exclusion. This places two obligations on the clinician: first, to exclude other conditions that may mimic it and, secondly, to search for possible aetiological clues in individuals suffering from it. The differential diagnosis includes recurrent pulmonary thromboembolism, tumour embolism, pulmonary arteritis related to collagen diseases and, of course, pulmonary hypertension secondary to primary heart or lung disease. The characteristics of these conditions are discussed elsewhere in this chapter. Possible aetiological factors are discussed below.

While very rare spontaneous remissions have been reported [69], the untreated course of primary pulmonary hypertension is one of rapid deterioration to death, in part reflecting the fact that symptoms and signs are usually only detected at a late stage in its evolution [48,70]. The

**Fig. 26.4** Proximal pulmonary arterial dilatation, right ventricular enlargement and avascular lungs in patient with primary pulmonary hypertension.

median survival from diagnosis is about 2 years and only 10% survive as long as 10 years. Death results from progressive hypoxaemia and right-sided heart failure, often occurring in a sudden syncopal episode.

#### *Pathology*

The pathological changes consist of medial hypertrophy of the muscular pulmonary arteries, muscularization and reduplication of the elastic laminae of arterioles, and often extensive obliterative intimal proliferation [71–73] (Fig. 26.5). Characteristic of the condition, and distinguishing it from hypoxic pulmonary hypertension, is the presence of plexiform lesions, concentric laminar intimal fibrosis and non-inflammatory fibrinoid vasculosis (Fig. 26.6). The plexiform lesions appear to represent irregular recanalization of obliterated arterioles, and when this triad of pathological features is present the condition is characterized by pathologists as ‘plexogenic pulmonary hypertension’. It is also found in patients with pulmonary hypertension secondary to cardiac shunts and to hepatic cirrhosis. The changes in the heart and main and elastic pulmonary arteries do not differ from those in other forms of acquired pulmonary hypertension.

Having described the classical features of the disease, it is right to point out that about 50% of patients diagnosed in life as having primary disease are disclosed after death

as having suffered from thrombotic disease, be it embolic or due to *in situ* clot formation [48]. This is the case even when careful clinical steps are taken to exclude venous thrombosis, and is a justification for carrying out open lung biopsy if the procedure is thought to be acceptably safe.

#### *Aetiology*

From the foregoing, it is important to remember that a proportion of patients with what appears clinically to be primary disease in fact have thromboembolic disease. This apart, the cause of the condition is not known. Its association with Raynaud’s disease suggests that in a proportion it may be a manifestation of generalized hyperreactivity of small vessels [62]. Similarly, the association with liver disease suggests that circulating vasoconstrictor substances, normally metabolized in that organ, may be responsible [56,74]. Perhaps in keeping with this, excess levels of endothelin 1, a pulmonary vasoconstrictor, have been found in the endothelium of patients with plexogenic pulmonary hypertension [75]. The predominance of the condition in females of reproductive years has given rise to the theory that female sex hormones may be responsible in some way [76], and this has been supported by the excess risk of pulmonary hypertension (and of thromboembolism) in earlier users of contraceptive

pills [77,78]. The fact that primary pulmonary hypertension may occur in families has pointed to a genetic predisposition; in familial cases it may be inherited as an autosomal dominant or recessive [50,79,80]. Finally, the occurrence of an epidemic in Europe in association with use of the appetite suppressant aminorex [81,82] has led to a search for other drug- and food-induced episodes. Fenfluramine, several other anorexigens and phenformin appear to have been associated with the disease [83–85]. In most cases the hypertension has been reversible on stopping treatment, although this is not always the case [86]. Seeds of the various species of *Crotalaria*, a plant that grows widely in tropical and subtropical regions, have

been shown to be a potent cause of pulmonary hypertension in rats and have thus provided a useful and much-exploited model of this rare disease [87]. Interestingly, aminorex itself has not produced pulmonary hypertension in rats or dogs [88].

It is perhaps reasonable to assume that reactivity of the pulmonary vasculature is distributed as a continuous variable in the population, and that some individuals are particularly susceptible to a number of potential causes of muscular contraction. Thus, in susceptible individuals, hypoxia, drugs or components of the diet may provoke sufficient muscular constriction to raise vascular resistance. Some support for this concept comes from the

description of plexogenic pulmonary hypertensive changes in the lungs of patients with familial high-altitude disease [39]. Another hypothesis is that some individuals develop disease as a result of a disturbance in the normal balance between vasodilator and vasoconstrictor influences in the pulmonary circulation, either circulating substances or endogenously produced mediators in vascular endothelium. While both these hypotheses are plausible and far from mutually exclusive, they raise the question as to what environmental factors are responsible for the disease developing in some and not in others. Nevertheless, the concept of increased active vasoconstriction has led to important advances in the management of the condition, as discussed below.

### Management

The first step in management is establishment of the diagnosis or, rather, exclusion of other conditions such as thromboembolism, sleep apnoea and primary heart and pulmonary diseases. This leaves the possibility of undiagnosed thrombosis and thus most authorities recommend treatment with long-term anticoagulants [48,89,90]. These should also prevent the occurrence of secondary *in situ* thrombosis. The second step is to establish whether a response occurs to pulmonary vasodilators. Inevitably, lack of controlled trials and no doubt selective reporting of small series of patients in the literature allow only general guidelines to be given. However, a response of a greater than 20% fall in vascular resistance may occur in up to one-third of patients, indicating possible longer-term responsiveness [91,92]. Therefore during catheterization the acute response to vasodilators should be assessed, as was done in the earliest studies of this condition [63,64]. Initially acetylcholine and tolazoline were used, but nowadays prostacyclin, adenosine or nitric oxide are the methods of choice [93–97]. All seem approximately equally effective. While nitric oxide may have fewer side-effects, it seems sensible to use the drug with which the physician has greatest experience; currently prostacyclin is the one favoured in most centres. Verapamil and hydralazine are no longer used for this purpose as they have been associated with a number of sudden deaths [98,99].

Long-term treatment with vasodilators has recently shown promise as effective management of this serious disease. Intravenous prostacyclin has been shown to increase survival and quality of life, although not without complications including sepsis derived from the intravenous delivery system [100–102]. However, this is very expensive treatment. High doses of calcium channel antagonists have now become the favoured treatment, and have been shown to produce falls in pulmonary resistance and substantial improvements in survival and quality of life in around one-quarter of patients [103,104].

This form of treatment requires careful adjustment of the dose, as fatal falls in systemic blood pressure can occur. Nifedipine and diltiazem seem to be the drugs of choice. Adenosine has also been used to supplement the effects of these drugs in patients who respond with a fall in vascular resistance [105]. Nitric oxide is a relatively safe vasodilator and can be used by inhalation, thus having no systemic effects [106,107]. As mentioned above, it has been used to assess reversibility of pulmonary vascular resistance [93]; in one case, it was administered by mask and then transtracheal catheter for 2 months while the patient was awaiting transplantation [108].

The greatest advances in management have resulted from the availability of transplantation for patients not responding, or responding inadequately, to vasodilator therapy. The first reports of successful surgery were published in the 1980s, involving transplantation of heart and lungs [109,110]. Since then it has become apparent that lung transplantation is to be preferred and that the right ventricle will recover if the graft is successful [111–114]. Recent studies have investigated the relative advantages of single and double lung transplantation, and it seems likely that in experienced hands good short-term and medium-term responses may be expected in both procedures [115], although there are haemodynamic advantages to the double lung operation [113,116,117]. This is discussed further in Chapter 59.

A scheme for the management of primary pulmonary hypertension is given in Fig. 26.7. It should be clear from this discussion that once the diagnosis of primary pulmonary hypertension is suspected, patients should be referred to a centre with special experience and with transplantation facilities, if such is available. The aim of management in the initial stages should be to establish whether clinical and haemodynamic benefits occur in response to treatment with vasodilators and anticoagulants [89]. Most authorities use a careful trial of prostacyclin and, if a response occurs, follow it with nifedipine or diltiazem, the dose being titrated to produce maximum haemodynamic benefit short of unacceptable side-effects. A proportion of responders improve significantly; those that do not, together with non-responders, should be assessed for lung transplantation.

### *Pulmonary hypertension associated with connective tissue disease*

Some 20–30% of patients presenting with apparent primary pulmonary hypertension show evidence of a more general vascular or connective tissue disease [62]. The associations with Raynaud's syndrome and cirrhosis have been mentioned [56,57,62]. It may also be a feature of the CREST (calcinosis, Raynaud's, (o)esophagitis, sclerodactyly, telangiectasia) syndrome and of full-blown systemic sclerosis [118,119]. Systemic lupus erythematosus

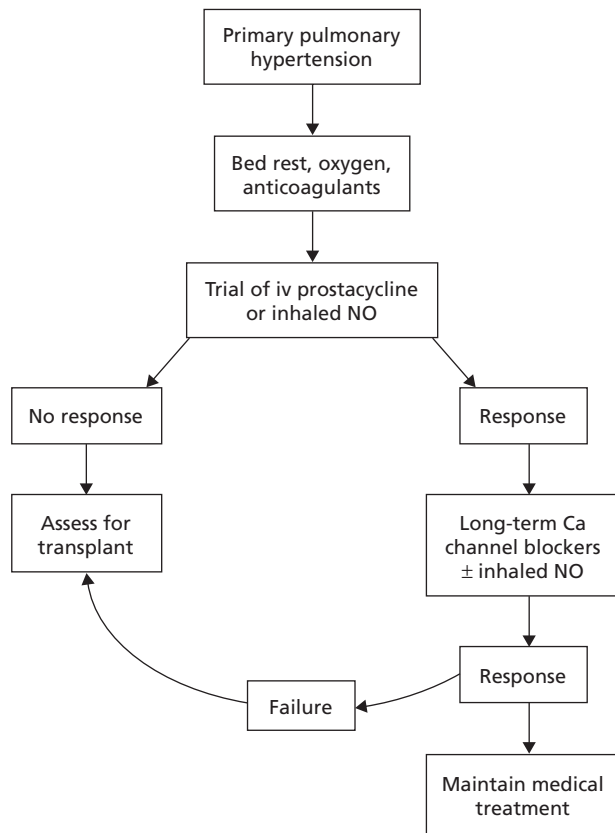

Fig. 26.7 Scheme for the management of primary pulmonary hypertension.

may occasionally be associated with pulmonary hypertension [120,121], especially when the syndrome includes the presence of the lupus anticoagulant, an immunoglobulin paradoxically associated with prolonged clotting time *in vitro* and a tendency to thrombosis *in vivo* [122]. It seems likely that the pulmonary hypertension in this syndrome is related to recurrent embolism or *in situ* thromboses [123–126]. An association of pulmonary hypertension with rheumatoid arthritis has also been described in one patient [127].

#### Embolic and other occlusive causes of pulmonary hypertension

Pulmonary embolism is discussed in Chapter 25. As noted above, a proportion of patients with apparently primary pulmonary hypertension are discovered at necropsy or on angiography to have had either multiple pulmonary emboli or possibly extensive *in situ* thromboses in small arteries [48,128]. Other patients may be detected clinically to have pulmonary hypertension as a result of repeated emboli from a recognizable venous thrombosis [129]. Embolic pulmonary hypertension may also occur in schistosomiasis and filariasis (see Chapter 22) and, rarely, as a result of disseminated tumour (see Chapter 42). Sick cell

disease and thalassaemia may also rarely cause *in situ* pulmonary arterial thromboses and lead to pulmonary hypertension [130,131]. The myeloproliferative disorders polycythaemia rubra vera and essential thrombocythaemia have also been shown to be associated with (probably thrombotic) pulmonary hypertension in a proportion of patients [132].

Acute massive pulmonary embolism is not associated with pulmonary hypertension, as the thin-walled right ventricle is incapable of generating sufficient pressure; right heart failure is the usual consequence. Moreover, since most such episodes are followed by either death or lysis of the emboli, very few appear to progress to chronic pulmonary vascular obstruction [129,133]. Somewhat more commonly, chronic venous thrombosis is associated with small, repeated and asymptomatic lung embolism. These patients usually only present at the stage when severe pulmonary hypertension has developed, the symptoms and signs being those of the primary condition [134–136]. Treatment is along the lines suggested for primary pulmonary hypertension, and the prognosis is apparently no better. Occasionally, when pulmonary angiography demonstrates widespread proximal arterial occlusion, removal of clot under cardiopulmonary bypass may prove feasible [137–139]. Sometimes the finding of reversible pulmonary hypertension at catheterization may suggest a response to vasodilators [89].

Multiple tumour embolism leading to pulmonary hypertension is a rare but well-described syndrome. The history may be quite short, the patient presenting with dyspnoea, and the radiograph may be normal. The primary tumour has most commonly arisen in breast, prostate, gastrointestinal tract or chorionic tissue [140–142]. Some such tumours, if recognized to be causing pulmonary hypertension early enough, may be susceptible to hormones or chemotherapy; a survivor of chorioncarcinoma embolism has been reported after such treatment [143]. In general, however, the syndrome is rapidly fatal.

#### Pulmonary veno-occlusive disease

##### Clinical features

In a small proportion of patients with obstructive pulmonary hypertension, the site of obstruction is found in the pulmonary veins. The patients present with progressive dyspnoea and eventually develop right-sided heart failure. The condition is no commoner in either sex, but is most usually seen in children and young adults [144–148]. In some there is a history of a preceding influenza-like illness and cases have been described in association with Hodgkin's disease [149], following chemotherapy with bleomycin and other drugs for neoplasms [150–152], and rarely after mantle radiation [153] and, in combination

with hepatic veno-occlusive disease, in bone marrow graft recipients [154]. It has also been described as one cause of pulmonary hypertension in human immunodeficiency virus (HIV) infection [155] (see below).

The clinical signs are those of pulmonary hypertension, although inspiratory crackles of pulmonary oedema and signs of pleural effusion may be present. Finger clubbing has been described but is not usual. The chest radiograph shows prominent proximal pulmonary arteries, Kerley's A and B lines and nodular opacities of pulmonary haemosiderosis (Fig. 26.8). The ECG shows evidence of right ventricular hypertrophy and the lung scan shows irregular diffuse areas of underperfusion. A bronchoscopic feature of intense hyperaemia of segmental and subsegmental bronchi has been described [156]. At catheterization, the pulmonary arterial pressure is high but the wedge pressure may be difficult to obtain and may be raised or normal.

The clinical and radiographic signs are usually distinctive; if the radiograph is seen first, the physician will anticipate finding evidence of mitral stenosis and, in the absence of appropriate signs, this issue can be settled with echocardiography and right heart catheterization. On finding pulmonary hypertension, reversibility should be sought as described above. Open lung biopsy is usually necessary to confirm the diagnosis [146,149]. In one reported case, the clinical features of veno-occlusive disease were shown at postmortem to have been due to obliteration of the veins by sarcoid granulomas [157]. Sarcoidosis should therefore be included in the differential diagnosis.

The course of the disease is progressive and fatal. In many instances death occurs within 2 years of the onset of symptoms, although in some patients the illness has lasted up to 7 years [144,158]. Isolated reports have suggested the possibility of response to anticoagulants [159] and azathioprine [160]. Vasodilators have also been shown to produce improvement in a number of cases and should always be tried [149,161,162]. If this is unsuccessful, the option of lung transplantation should be considered [163].

#### *Pathology and pathogenesis*

The principal pathological lesion is partial obliteration of multiple pulmonary veins, from large ones to venules. The vessels contain acellular fibrous strands and organized thrombus showing different degrees of recanalization. Some medial hypertrophy occurs in the veins with internal and external elastic laminae [144,164,165]. The arteries show much less change, although some medial hypertrophy and intimal proliferation may occur and occasionally thromboses are also present. The changes in the veins are distributed throughout the lung, though this distribution may be patchy. The lungs themselves show congestion, with haemosiderosis and patchy interstitial pneumonitis with leucocytes, monocytes and plasma cells [158,164,166], with possible development into pulmonary fibrosis. The right chambers of the heart are dilated and hypertrophied.

The cause or causes of the syndrome are not known. The possibility that it is a reaction to viral infection has been referred to above, as has its relationship with bleomycin

**Fig. 26.8** Chest film of patient with pulmonary veno-occlusive disease, in this case thought to be secondary to Hodgkin's disease, showing pulmonary arterial dilatation, right basal effusion and Kerley's lines. (Courtesy of Dr David Ellis.)

and radiation therapy. Familial and congenital cases have suggested the possibility of intrauterine infection [167,168]. No obvious coagulation disorder has been described, although in one case evidence of an immune complex-mediated condition was adduced [169]. Finally, bush teas containing *Crotalaria* alkaloids have been described as causing veno-occlusive disease of the liver in West Indians [170]; however, these agents cause pulmonary arterial disease experimentally in rats and have not been shown to cause pulmonary venous obliteration in humans. It has been suggested that the common endpoint of a number of causative factors may be damage to the endothelium of the pulmonary veins, depleting its content of plasminogen activator and thus inhibiting normal clot lysis [171]; this remains speculative.

### ***HIV infection***

Since the late 1980s there have been a number of reports of cases of apparent primary pulmonary hypertension in patients with HIV infection [172–174]. It is very likely that this is a specific consequence of the infection itself rather than one of its infective complications [175]; in support of this, mild pulmonary hypertension has been produced in an experimental mouse model [176]. The clinical features and pathology do not differ from those of the idiopathic disease [175,177], and in some cases a response to vasodilators has been documented [177]. One report has documented pulmonary veno-occlusive disease [155], but in the other cases the pathological lesion has been on the arterial side. The virus has not been demonstrated in the vascular endothelium, suggesting that the mechanism may be related to more peripheral release of mediators.

### **Increased pulmonary venous pressure**

The causes of increased left atrial pressure are all, except one, cardiac conditions and are only mentioned here briefly; detailed descriptions can be found in cardiological textbooks. The exception is the very rare obstruction of the pulmonary veins by mediastinal fibrosis [178] (see Chapter 49). While a raised left atrial pressure of necessity causes a rise in pulmonary arterial pressure, this rise is often accentuated by reactive changes in the pulmonary vasculature. Thus the patient's likelihood of developing pulmonary oedema according to Starling's law (see Chapter 27) is reduced at the cost of the eventual development of right-sided heart failure. The pathological changes in the lungs of patients with pulmonary hypertension due to raised left atrial pressure are characteristic.

### **Mitral valve disease**

Mitral stenosis is usually caused by rheumatic disease and

is still a common condition in many subtropical parts of the world. Its importance to the respiratory physician is in differential diagnosis, since patients typically present with a history of increasing breathlessness, cough and sputum production [179]. Since winter exacerbations of bronchitis and haemoptysis are common symptoms, such patients are not infrequently referred to chest physicians. Diagnosis may be complicated by the frequent occurrence of airflow obstruction in the condition. The physical signs are characteristic, with tapping apex beat (due to a palpable first heart sound), right ventricular lift, accentuated first sound, opening snap and apical diastolic murmur. The ECG often shows right ventricular hypertrophy and P mitrale in pure stenosis, while the chest radiograph shows enlarged left atrium and pulmonary arteries, diversion of pulmonary perfusion to the upper zones (a feature well shown on xenon lung scans) and often signs of pulmonary oedema and Kerley's lines (Fig. 26.9). These classical features may be less obvious when severe pulmonary hypertension and right ventricular hypertrophy supervene and when there is a rigid calcified valve, when the auscultatory signs may disappear. However, echocardiography is a simple and reliable way of making the diagnosis and should always be used if the disease is suspected [180].

Mitral regurgitation often accompanies rheumatic mitral stenosis but may occur alone as a result of left ventricular disease, papillary muscle dysfunction or rupture of chordae tendineae. Regurgitation causes both pulmonary hypertension, secondary to raised left atrial pressure, and left ventricular hypertrophy and, eventually, failure.

Rare causes of mitral valve disease include congenital stenosis, often associated with congenital left-sided obstructive defects, congenital regurgitation in association with endocardial cushion defects (ostium primum atrial septal defect), Libman-Sacks endocarditis, and the hyper-eosinophilic syndrome [181,182]. An abnormal mitral valve may also be the site of bacterial endocarditis. The pathological changes in the lung in mitral valve disease include dilatation of proximal pulmonary arteries and narrowing of the lower zone elastic arteries with intimal fibrosis and often atheroma [183,184]. Medial hypertrophy of muscular pulmonary arteries is also most marked in the lower zone vessels. Arterioles show a muscular media and intimal thickening, capillaries and lymphatics are much dilated, and veins show medial thickening and appearances that make them difficult to distinguish from muscular arteries. Pulmonary haemosiderosis and sometimes ossification may be seen. All changes are most marked in the lower zones, where vascular obliteration and *in situ* thrombosis may occur, but plexiform lesions are not seen.

**Fig. 26.9** Chest film of patient with mitral stenosis showing left atrial shadow behind right atrium and Kerley's B lines.

#### Other causes of raised left atrial pressure

Any cause of left ventricular dysfunction raises left atrial and therefore pulmonary arterial pressure. These diseases are rarely sufficiently chronic for the pulmonary hypertension ever to become more than an incidental feature and reactive changes in the pulmonary vessels are rare. However, two conditions may mimic mitral stenosis in pathophysiological effects, left atrial myxoma and cor triatriatum.

Myxoma is a rare non-malignant cardiac tumour arising from the atrial septum, in most cases in the left atrium [185]. It is pedunculated and may present by causing symptoms and signs identical to those of mitral valve disease, including systemic embolization, or by producing systemic symptoms such as fever and weight loss mimicking bacterial endocarditis. It may cause prolonged mitral valve obstruction and lead to pulmonary hypertension but this is unusual. It is diagnosed by echocardiography. Cor triatriatum is a congenital anomaly in which the left atrium is divided by a membrane into two chambers, one receiving the pulmonary veins and the other connecting with the mitral valve [186]. The passage through the membrane may be very small, causing severe pulmonary venous hypertension from birth. Again, diagnosis is by echocardiography.

#### Increased pulmonary blood flow

As stated above, pulmonary blood flow may increase considerably without increase in the pressure in the circuit because of the spare capacity of the capillary bed. The conditions associated with increased flow, i.e. congenital and occasionally acquired left-to-right shunts, do not cause a serious rise in pulmonary pressures until reactive changes occur in the vessels. Once this happens, the pulmonary pressure may rise to systemic levels and the shunt reverse. These conditions rarely present initially to the chest physician, although most do see occasional examples presenting as pneumonia with right-sided endocarditis.

#### Atrial septal defect

The more common ostium secundum defect may remain undiscovered until adult life, when the clinical features may be confused with those of cor pulmonale [187]. Symptoms of breathlessness, cough and palpitations do not usually occur until the fourth and fifth decades. The physical signs include a systolic click and pulmonary flow murmur, with a fixed split of the second heart sound. The ECG shows partial right bundle branch block and P pulmonale. The chest radiograph shows plethoric lungs, big pulmonary arteries and large right atrium and ventricle.

(Fig. 26.10). The increased pulmonary blood volume is reflected by a raised diffusing capacity on lung function testing. Ostium primum defects involve the mitral and tricuspid valves as well as the atrial septum; they usually present earlier in life and have additional signs of mitral regurgitation. The ECG shows a characteristic left axis deviation with partial right bundle branch block.

Both conditions may progress to cause pulmonary hypertension and eventually reversal of the shunt, the Eisenmenger syndrome. Before this occurs the pathological changes in the vascular bed are minimal, but with more severe hypertension muscularization of arterioles, medial hypertrophy of muscular arteries and marked endothelial proliferation are seen [188]. Very severe hypertension may be associated with secondary arterial and arteriolar dilatation and the development of plexiform lesions. Characteristic intimal fibrosis of pulmonary veins is seen.

### Post-tricuspid shunts

The two important post-tricuspid shunts that persist into

adult life are ventricular septal defect and patent ductus arteriosus. Ventricular septal defect may be acquired following infarction of the septum, although this causes acute pulmonary oedema rather than chronic pulmonary hypertension. Usually, the lesion is congenital and left-to-right shunting occurs when the pulmonary resistance drops naturally at birth. The increased pulmonary flow may result in pulmonary oedema in the first few weeks of life, but in many patients this is prevented by cessation of the normal involution of medial muscle in the muscular pulmonary arteries and therefore an increase in vascular resistance. In about 25% of patients the defect may close naturally as a result of muscular growth of the septum; in about 5% the shunt may be reduced by progressive stenosis of the infundibulum of the right ventricle. About 5% of patients go on to develop irreversible pulmonary hypertension and shunt reversal, usually in the second and third decades of life [189]. The symptoms are increasing exertional dyspnoea, faints, haemoptysis and, ultimately, cyanosis and clubbing. Before symptoms develop, the characteristic loud, left parasternal murmur obscuring the

**Fig. 26.10** Atrial septal defect before shunt reversal showing huge proximal pulmonary arteries, plethoric lungs and enlarged right atrium.

heart sounds and a mid-diastolic apical flow murmur are heard. The ECG may show left or right ventricular hypertrophy, depending on the stage of the disease, while the chest radiograph may show biventricular enlargement and pulmonary plethora. Before pulmonary hypertension supervenes, the carbon monoxide diffusing capacity is raised, reflecting the increased pulmonary blood volume.

It should be pointed out that in about half of all patients with persistent ventricular septal defect the shunt is small and the patient symptomless. The main hazard of this condition is bacterial endocarditis and precautions to prevent this are necessary. Most other patients are now operated on in infancy or childhood and shunt reversal is seen only rarely in the West.

The pathological changes in the pulmonary vessels reflect the stage and severity of the disease. In patients with pulmonary hypertension there is persistence of the

fetal pattern of muscle in the muscular pulmonary arteries [188]. Further progression is accompanied by medial hypertrophy and intimal proliferation, leading to progressive occlusion of muscular arteries and arterioles and the development of plexiform lesions [188].

Patent ductus arteriosus may present at any age, although left ventricular failure in infancy or childhood is most usual. The characteristic machinery murmur maximal in the second left intercostal space, together with a high-volume water-hammer pulse and radiographic changes of pulmonary plethora and left ventricular hypertrophy, usually make the diagnosis easy. Treatment is by surgery and few patients now go on to develop bacterial endarteritis or pulmonary hypertension. The latter outcome is associated with shunt reversal and clinical and pathological features like those occurring at the same stage of ventricular septal defect.

# PULMONARY OEDEMA AND ADULT RESPIRATORY DISTRESS SYNDROME

CHRISTOPHER HASLETT

Pulmonary oedema is defined as an excess of extravascular water within the lung. This fluid may accumulate within the interstitial tissues, in alveolar walls and around vessels (interstitial oedema), within alveoli (alveolar oedema), or commonly both. Oedema may accumulate as a consequence of increased permeability of small vessels and alveolar walls or because of increased hydrostatic pressure in the small pulmonary vessels; blockage of lung lymphatics and reduction of plasma protein concentrations may also contribute occasionally. Thus two essentially different types of pulmonary oedema may be recognized clinically, high-pressure oedema and increased permeability oedema. The latter type has been called the adult respiratory distress syndrome (ARDS) [1,2].

## Anatomy and physiology

The alveolar epithelium is lined by flat type I pneumocytes that, although less frequent than the type II cells, constitute most of the alveolar surface area. These epithelial cells are connected by tight junctions, normally impermeable to fluid, and are coated on their alveolar surface by a waterproofing layer of surfactant. They are adherent to a basement membrane, which fuses in places with that of the capillary endothelial cells. The alveolar capillary is lined throughout with thin, flattened endothelial cells. The junctions between these cells are much less tight than those between the epithelial cells, thus allowing some permeation of fluid and solutes between them.

The fusion of epithelial and endothelial basement membranes is incomplete, and there is a thinner and a thicker side of the alveolar wall in relation to the capillary (Fig. 27.1). On the thin side, the membranes are fused and there is a minimal distance for gas diffusion, whereas on the thicker side the membranes are separated by an interstitial space. This space is in continuity with the spaces around the bronchovascular bundles, in the interlobular septa and under the visceral pleura, and leads therefore to the lymphatic drainage system of the lung.

As in other tissues and organs, so in the lung there is net movement of fluid from the capillaries and small precapillary and postcapillary vessels into interstitial tissue and thence via lymphatics back into the vascular compartment. This flow out of the microvasculature is determined by forces described in the Starling equation:

$$Q = K(P_{mv} - P_{pmv}) - \sigma(\pi_{mv} - \pi_{pmv}) \quad [27.1]$$

where  $Q$  represents the rate of flow of liquid,  $K$  the conductance of fluid across the barrier,  $\sigma$  the resistance of the barrier to passage of proteins,  $P_{mv}$  and  $P_{pmv}$  the microvascular and perimicrovascular hydrostatic pressures and  $\pi_{mv}$  and  $\pi_{pmv}$  the microvascular and perimicrovascular protein osmotic pressures. Under normal circumstances there is a small net flow of fluid with low protein content through the microvascular endothelium. This fluid is then transferred in the interstitial space towards the lymphatics and the peribronchovascular connective tissue space, the extra-alveolar interstitial tissue. It has been shown that a pressure gradient exists between this and the alveolar interstitial tissue [3], which together with the pumping action of respiration sucks fluid away from the alveoli. At the same time, fluid flow into the alveolar space is prevented by the tight junctions between epithelial cells and by the waterproofing action of surfactant. It has been estimated that every hour approximately 10–20 mL of fluid are removed by the lymphatics from the alveolar interstitial tissue in the normal human [4].

From this account, it can be seen that fluid accumulation occurs in the alveolar interstitial space if the hydrostatic pressure in the pulmonary capillaries is raised or if the endothelium of the capillaries becomes excessively leaky. In either case, lymphatic flow increases and excess fluid is also propelled into the extra-alveolar interstitial tissues, where it forms cuffs around bronchi and vessels. In the case of high-pressure oedema, the fluid has a low protein content and accordingly there is an increased osmotic force tending to reduce the rate of outflow. In the case of increased permeability oedema, the fluid is of relatively high protein content and this mechanism is less effective.

Fig. 27.1 The alveolar–capillary structures.

Translation of fluid from the alveolar interstitium to the alveolar airspaces is somewhat less easy to understand. It probably occurs because of leakage through the tight junctions resulting from the increasing interstitial pressure; it has been shown both in humans with disease and in experimental animals that the protein content of alveolar and interstitial fluid in these circumstances is identical and that the oedema fluid in left ventricular failure has a protein content about half that of plasma, suggesting that the normally impermeable membrane has lost its integrity [5–8]. It has been argued cogently that the normal alveolar surface lining is free of fluid and that the surfactant acts as a waterproofing layer, exerting a powerful force from within the airspaces to prevent ingress of water [9,10]. A rise in interstitial pressure, producing a gradient of above 2.7 kPa (20 mmHg) [11], may overcome these forces, allowing drops of water to seep through the otherwise tight junctions; sufficient drops would then merge to line the alveoli and the concave surface adopted would create a powerful force attracting more water. Alternatively, or perhaps in addition, the predominant site of leakage may be from extra-alveolar interstitial tissue through the rather more permeable bronchiolar epithelium and thence down into alveoli [12].

From Eqn 27.1 it can be seen that a fall in plasma osmotic pressure due to hypoproteinaemia may contribute to pulmonary oedema. This may occasionally be of relevance in humans, usually in association with other factors that tend to increase net outflow of fluid from the capillaries [13]. Other factors not considered by this equation may also make a contribution to the accumulation of oedema fluid in the lung. Clearly lymphatic blockage, as may occur in malignant infiltration [14], is potentially important. However pleural effusions rather than pulmonary oedema are more characteristic of the lymphatic abnormalities that occur in the yellow nails syndrome [15]. Less obviously, the perfused alveolar surface area may be rele-

vant, in that a greater area implies a greater total amount of fluid flow. Pulmonary lymphatic flow has been shown to increase in exercising sheep, presumably in relation to increased pulmonary capillary perfusion [16]. The relevance of this, if any, to human disease is unclear.

Clearance of excess fluid from the interstitial space depends on increased lymphatic flow once leakage has been reduced by appropriate therapeutic measures. However, clearance from the alveolar spaces is less easy to envisage. Some fluid may be transported into the airways and cleared by cough, as witnessed by the frothy sputum produced in left ventricular failure. Some, probably the majority in most cases, appears to be reabsorbed into the interstitial space. That this occurs despite the apparently tight junctions between epithelial cells suggests some active mechanism, and it has been suggested that water and electrolytes may be pumped actively back through the epithelial cells [17]. However, there is also evidence of some return of protein from alveoli [18], and consideration of the likely physical factors involved has led to the suggestion that surface tension may well provide sufficient force to impel fluid back between the cells, just as increased interstitial pressure forced it out originally [10]. This theory suggests that while a thin continuous layer of fluid in alveoli produces a force attracting more fluid in, if this layer is broken up (e.g. by stretching due to positive end-expiratory pressure ventilation) the presence of the hydrophobic surfactant coating beneath the fluid layer results in the formation of bubbles, rather like drops of water on a non-stick frying pan. These drops form in corners of alveoli where their surfaces generate powerful positive pressures, up to several hundred mmHg; this can be sufficient to overcome the resistance of the epithelium together with the negative oncotic force exerted by protein in the oedema fluid. Some morphological evidence that such droplets might form in the smallest airways was published 30 years ago [19].

While water and electrolytes seem able to be removed relatively easily from alveoli, proteins are clearly removed more slowly and less efficiently. The transudate of high-pressure pulmonary oedema presents less of a problem than the higher-protein fluid of increased permeability oedema, and experimental studies have shown increasing protein concentration (and therefore osmotic pressure) as the fluid is removed [20,21]. In such circumstances, the remaining protein may well contribute to the hyaline membranes frequently found lining the alveoli at autopsy [21].

High-pressure oedema

Cardiogenic pulmonary oedema is a syndrome familiar to all doctors. In brief, the important clinical features are shortness of breath, orthopnoea, paroxysmal nocturnal dyspnoea and cough. The condition may present with an acute episode, which commonly starts with cough and tachypnoea and is often associated with wheezing or with steadily increasing exertional dyspnoea and orthopnoea. In acute attacks, frothy (sometimes pink) sputum may be produced. The patient is anxious and cyanosed, and signs of the primary cardiac lesion together with bilateral basal repetitive inspiratory crackles and sometimes wheezes are found. In chronic disease, repetitive basal crackles are usually the only pulmonary sign.

The most common causes are shown in Table 27.1. Acute cardiogenic pulmonary oedema is usually due to myocardial infarction or hypertensive heart disease, and less frequently to rupture of the aortic valve or left ventricular

septum, cardiomyopathy or left atrial myxoma. Acute episodes may also occur as a consequence of acute dysrhythmias and because of fluid overload, due to either overzealous infusion or renal failure. Chronic pulmonary oedema is most usually seen with aortic and mitral valve disease, cardiomyopathy and ischaemic myocardial disease. Veno-occlusive disease is a rare cause [22]. Pulmonary oedema of high altitude and that related to acute neurological disease are also probably in part mediated by a high pulmonary capillary pressure.

Radiological features

The radiological signs of interstitial oedema usually appear before clinical signs of pulmonary oedema are obvious [23,24]. The early signs are blurring of the normally clear outlines of the main pulmonary vessels, diffuse pulmonary clouding and the presence of Kerley's A and B lines (see Figs 7.46 & 7.47). The vascular blurring relates to the presence of perivascular interstitial fluid; cuffing of vessels and bronchi seen *en face* may also result from the same mechanism. Kerley's lines relate to fluid accumulation in and around lymphatics in interlobular septa. As the oedema increases, nodular opacities and ultimately signs of alveolar consolidation appear (Fig. 27.2). While increased density at the hila, the so-called 'bat's-wing' appearance, is characteristic, other patterns may be present and lateral asymmetry is not uncommon.

Other radiological signs may accompany those of the pulmonary oedema. Evidence of the primary cardiac disease, usually with left ventricular enlargement, is often present. Increased left atrial pressure and pulmonary interstitial pressure cause reduction of pulmonary arterial perfusion to the dependent part of the lung and thus diversion of flow through the upper zones; the upper zone vessels therefore appear relatively enlarged. Pleural effusion is also a frequent accompaniment of left ventricular failure. It is usually predominantly right-sided; in the absence of right-sided pleural obliteration, a unilateral left pleural effusion in heart failure should alert the physician to the presence of other disease such as pulmonary embolism. Finally, an increased intravascular blood volume may be detected by widening of the vascular pedicle, measured from a perpendicular dropped from the lateral origin of the left subclavian artery across to the lateral margin of the superior cava as it crosses the right main bronchus. The normal distance in the upright adult is 48±5 mm (26).

Diagnosis and management

Investigation of high-pressure pulmonary oedema consists essentially of differentiating it from other causes of similar clinical and radiological signs and then investigating the primary cause. Difficulties arise in early cases or

**Fig. 27.2** Severe bilateral cardiogenic pulmonary oedema showing 'bat's-wing' appearance. (From Simon & Wightman [25] with permission.)

when several conditions coexist, a frequent problem in the elderly. An abnormal ECG is almost invariably present in acute cardiogenic pulmonary oedema, together with clinical signs of the cardiac disorder. In patients in whom both cardiac failure and increased permeability oedema are serious possibilities, as with postoperative complications, extensive trauma and overwhelming infection, a percutaneous catheter floated through the pulmonary artery to record the wedge pressure is invaluable. Some points helpful in differentiating high-pressure and increased permeability oedema on the chest radiograph are listed in Table 27.2. These signs are not, of course, absolute, but taken together often allow a reasonably confident radiological diagnosis of the type of oedema.

As would be expected, the functional effects of high-pressure oedema are a reduction in lung compliance and lung volumes. Hypoxaemia is an invariable feature and this may be accompanied by hypocapnia; a metabolic acidosis may occur simultaneously because of reduced tissue oxygenation. Not infrequently, however, especially in the elderly, arterial hypercapnia may supervene in relation to increased lung stiffness and failing respiratory effort [27,28].

The management of high-pressure oedema is essentially that of the primary condition together with administration of diuretics and oxygen. The traditional therapy with morphine still has a place in acute left ventricular failure, although venesection and the use of cuffs have given way

**Table 27.2** Radiological differentiation of high-pressure and increased permeability pulmonary oedema.

	High-pressure	Acute lung injury

Air bronchograms	Unusual	Frequent

to peripheral vasodilators. Furosemide (frusemide) is the diuretic of choice because of its rapid action and its ability to increase the capacitance of the venous bed, diverting blood from the pulmonary circuit. This explains why relief of symptoms and fall in pulmonary wedge pressure may take place following intravenous administration before diuresis occurs. The positive inotropic effect of digitalis should not be forgotten in treating left ventricular failure; together with its antiarrhythmic effect this ensures that it remains a valuable drug when given in adequate digitalizing dosage. However, care must be exerted in its use following acute myocardial infarction when it may induce ventricular dysrhythmias.

High flow rates of oxygen are essential in the management of high-pressure oedema and these are safe even if the  $\text{Paco}_2$  is raised (unless there is evidence of severe airflow obstruction as well). Positive-pressure ventilation

is rarely necessary in this type of pulmonary oedema, in contrast to the situation with increased permeability oedema; it is effective in improving oxygenation, although it may impair venous return and further depress cardiac output.

### Adult respiratory distress syndrome

The first detailed clinicopathological description of ARDS was provided by Ashbaugh and colleagues [1], who in 1967 identified a subgroup of patients who could be differentiated from the majority of patients requiring intensive care management for severe respiratory failure using the following features:

- 1 tachypnoea and cyanosis refractory to oxygen treatment;
- 2 markedly reduced lung compliance on mechanical ventilation;
- 3 diffuse alveolar shadowing on the chest radiograph (Fig. 27.3);
- 4 pulmonary oedema, congestion and hyaline membranes on histological examination of necropsy specimens.

The syndrome was described as 'acute respiratory distress in adults' [1], and later in a more detailed analysis as 'adult respiratory distress syndrome' to distinguish it from a similar pathological condition in premature neonates [2]. However, it is likely that acute lung injury as a complication of severe trauma was recognized in both world wars and perhaps before [29]. In the tenth edition of his classic text *The Principles and Practice of Medicine* published in 1927

[30], William Osler remarked that 'uncontrolled septicaemia leads to a frothy pulmonary oedema that resembles serum, not the sanguineous transudative oedema fluid of...congestive cardiac failure'. Military surgeons in both world wars observed that previously healthy young men sometimes developed pulmonary oedema as a grave and usually fatal complication of non-pulmonary trauma. Indeed, this extract from the poem 'Dulce et decorum est' by the First World War poet Wilfred Owen refers to just such a case of toxic gas inhalation:

And watch the white eyes writhing in his face,  
His hanging face, like a devil's sick of sin;  
If you could hear, at every jolt, the blood  
Come gargling from the froth-corrupted lungs

The link between pulmonary oedema and severe head injury was made in the First World War. During the Second World War the association between 'wet lung' and injury of the long bones and abdomen was also increasingly recognized [31]. As observed by a modern authority on ARDS, John Murray [32], it is likely that the increasingly heroic and effective battlefield surgery in the Second World War and the use of 'Medevac' in the Vietnam War to transport the severely wounded rapidly to base hospital were factors in the increased recognition of this catastrophic complication, often called 'shock lung', in patients who hitherto would have died from their injuries. It must have been extremely distressing for the surgeons to perform life-saving surgery only to find that a significant subgroup of otherwise healthy individuals subsequently died from this late complication.

It is now widely accepted that ARDS is a syndrome of

**Fig. 27.3** Adult respiratory distress syndrome occurring in the left lung after right pneumonectomy for bronchial carcinoma.

acute inflammatory lung injury that can be initiated in pulmonary microvessels as a result of a wide variety of insults to the lung, either directly (such as toxic gas inhalation) or indirectly (such as multiple trauma and sepsis) (see Tables 27.3 & 27.4). It is also clear that in most cases ARDS is part of a systemic syndrome of acute microvascular injury, now called multiple organ failure, in which the lung features heavily but which may also include renal failure and injury to the liver, gut and skin [33]. It occurs in an unpredictable fashion, often after a latent period of several hours or days. Despite the varied causes there appears to be a common histopathological picture, characterized as 'diffuse alveolar damage' (DAD). Full-blown ARDS is a devastating condition with a mortality of 50–70%, although recent data suggest that the mortality may be reducing somewhat, probably as a result of improvement in intensive care management [34]. Some of those who remain on a mechanical ventilator enter a chronic phase, with a strikingly early and dramatic fibroproliferative response and rapidly progressive scarring. Nevertheless, in the 30–50% who survive, there is often remarkable recovery of lung function [35]. Great strides are now being made in our understanding of the inflammatory mechanisms that lead to acute lung injury and it is hoped that this will generate incisive new mechanism-based therapies that could be applied during the latent period in the hope of abrogating or aborting full-blown lung injury.

### Definition

Now it is clear that ARDS embraces a spectrum of disease severity, i.e. a continuum rather than an all-or-nothing

event, it is perhaps not surprising that it has been difficult to set the limits for a stringent diagnosis. This difficulty is further compounded by the wide range of predisposing events that appear to initiate a common clinicopathological picture (Fig. 27.4). The original Murray definition rested on the following principles:

- 1 severe dyspnoea and hypoxaemia refractory to oxygen therapy because of marked right-to-left pulmonary shunting;
- 2 widespread shadowing on the chest radiograph indicative of alveolar oedema in the absence of cardiac failure (normal pulmonary capillary wedge pressure);
- 3 decreased lung compliance on mechanical ventilation.

This definition was, and still is, valuable particularly in identifying the cast-iron case of severe ARDS. However, it has always been recognized that there are many other patients who display the classic radiographic appearances and hypoxaemia but who are not sufficiently ill or whose illness is sufficiently transient not to require mechanical ventilation. There has been additional difficulty in setting appropriate limits for pulmonary wedge pressure, particularly as patients with ARDS could easily become overloaded with fluid during their initial management or could develop an additional element of cardiac failure. There is also a relationship between certain precipitating causes and outcome, for example sepsis-provoked ARDS is often associated with multiple organ failure and has a poor prognosis, whereas many patients who develop ARDS after near-drowning or opiate overdose appear to have a more benign, self-limited form of the disease [36]. Finally, some cases of established, full-blown ARDS may progress in an unpredictable fashion to a chronic fibroproliferative phase with rapid onset of scarring, sometimes

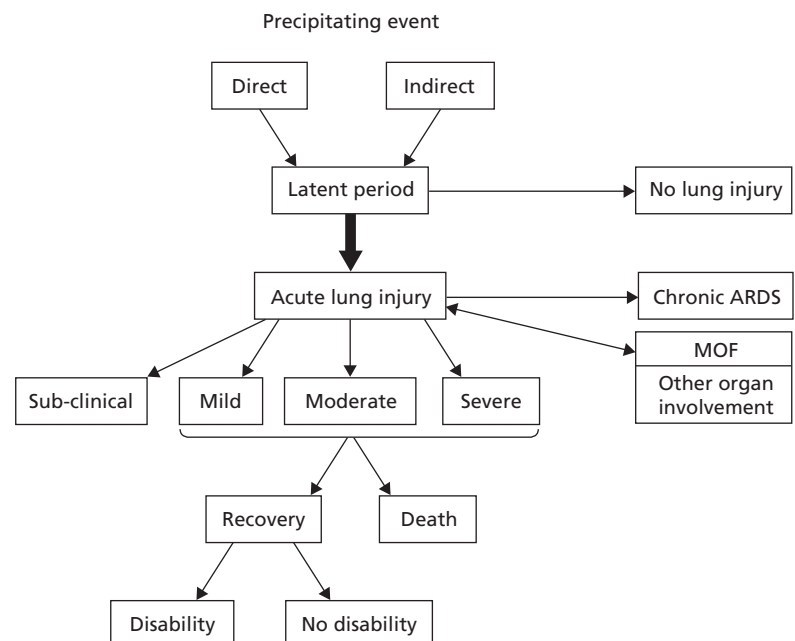

Fig. 27.4 The clinical spectrum of ARDS. MOF, Multiple organ failure.

within days. The recognition of this form of ARDS may have therapeutic implications (see below). A useful clinical definition of ARDS needs to account for these additional observations.

In order to take account of the variation in severity of lung injury, Murray's expanded definition includes a lung injury score that is now widely used [37] (Table 27.3). In 1992, an American–European conference was held to reach consensus on the clinical definition of ARDS. It was agreed that 'acute' should be substituted for 'adult' to account for the fact that this disorder can occur in children. However, the limitation to 'acute' fails to incorporate those patients who enter a chronic phase, recognition of which may be important since there could be additional therapeutic implications (see below). In the consensus criteria the Murray scoring system is simplified such that all patients with a  $P_{aO_2}/F_{iO_2}$  ratio of less than 200 are diagnosed as having ARDS (although this does not take into account any complicating effects of positive end-expiratory pressure)

**Table 27.3** Murray's lung injury score.

	Value
<i>Chest X-ray score</i>	
No alveolar shadowing	0
Alveolar consolidation confined to one quadrant	1
Alveolar consolidation confined to two quadrants	2
Alveolar consolidation confined to three quadrants	3
Alveolar consolidation confined to four quadrants	4
<i>Hypoxaemia score</i>	
$P_{aO_2}/F_{iO_2} \geq 300$	0
$P_{aO_2}/F_{iO_2}$ 225–299	1
$P_{aO_2}/F_{iO_2}$ 175–224	2
$P_{aO_2}/F_{iO_2}$ 100–174	3
$P_{aO_2}/F_{iO_2} < 100$	4
<i>PEEP score (when ventilated)</i>	
PEEP $\geq 5$ cmH <sub>2</sub> O	0
PEEP 6–8 cmH <sub>2</sub> O	1
PEEP 9–11 cmH <sub>2</sub> O	2
PEEP 12–14 cmH <sub>2</sub> O	3
PEEP $\leq 15$ cmH <sub>2</sub> O	4
<i>Respiratory compliance score (if available)</i>	
Compliance $\geq 80$ mL/cmH <sub>2</sub> O	0
Compliance 60–79 mL/cmH <sub>2</sub> O	1
Compliance 40–59 mL/cmH <sub>2</sub> O	2
Compliance 20–39 mL/cmH <sub>2</sub> O	3
Compliance $\leq 19$ mL/cmH <sub>2</sub> O	4
The final score is obtained by dividing the aggregate sum by the number of components that were included:	
No lung injury	0
Mild/moderate lung injury	0.1–2.25
Severe lung injury (ARDS)	$> 2.5$

ARDS, adult respiratory distress syndrome; PEEP, positive end-expiratory pressure.

and it was recommended that the definition should also be linked to the precipitating cause.

**Causes**

A very large number of widely diverse conditions have been implicated as causes of ARDS. It has been suggested [37,39] that these can be usefully segregated into *direct* precipitating events, for example certain pneumonias, toxic gas inhalation, etc. (Table 27.4) and *indirect* causes where the initiating insult is systemic or distant from the lung, for example pancreatitis, sepsis, etc. (Table 27.5). It is not yet possible to subclassify ARDS patients with regard to their pathogenesis since it seems, despite the diversity of precipitating events and sometimes different outcomes, that once lung injury begins there is a common pathological pattern of DAD. The segregation of precipitating events into direct and indirect has led to helpful insights into the circumstances and mechanisms by which insults distant from the lung, such as pancreatitis and severe burns, generate mediators and activate inflammatory cells that impinge on the lung and initiate the processes of endothelial and epithelial injury. Furthermore, direct causes such as inhalation of gastric acid are more likely to result in rapid onset of acute lung injury, whereas in multiple trauma or sepsis for example there is often a gap or latent period of several hours to 2 or 3 days before the patient develops clinically overt lung injury.

**Clinical spectrum**

The definition of ARDS thus includes patients at high risk

**Table 27.4** Direct causes of adult respiratory distress syndrome.

Anaphylaxis
Goodpasture's disease

who, after variable latent periods, develop acute lung injury that may be mild or severe. However, if the concept of a continuum of disease is accepted it is likely that among those at risk there will be a large number of patients with subclinical lung injury, some of whom might be detected by sophisticated imaging techniques for disclosing lung oedema whereas others may not be detectable by methods currently available (Fig. 27.4). Nevertheless the kinetic relationship between the subclinical disease group and the clinically overt group is important to our understanding of the pathogenesis of acute lung injury and also for planning clinical management. Thus the original Murray definition would include only those in the severest category, while the consensus criteria would include many more. However, if we think of ARDS as an iceberg, the concept of a continuum of lung injury suggests that the largest proportion may well be hidden beneath the surface (Fig. 27.5).

### Epidemiology

The prosecution of high-quality epidemiological research has been dogged by the vexed question of clinical definition, not only the diagnosis of ARDS but also the difficulty of achieving stringent diagnostic criteria for some of the most important predisposing conditions, such as 'sepsis syndrome'. Furthermore, the diagnosis of ARDS and its recording as a cause of death are likely to vary considerably between centres and particularly between different countries. Therefore, it is perhaps not surprising that the recorded incidence of ARDS even from the same precipitant cause may vary widely. Recent studies suggest an incidence of about 5–7 per 100 000 population per annum worldwide [40], 4.5 per 100 000 in England [41] but as low as 2 per 100 000 in the Canary Islands [42]. The latter study is likely to be an underestimate since patients under the age of 15 were excluded. It is generally held that the worldwide annual incidence of ARDS is about 5–7 per 100 000.

Studies in the USA suggest that the average patient is 49±2 years, white (2:1 white/black), male (3:2 male/female) and a non-smoker (2:1 non-smoker/smoker)

**Fig. 27.5** The ARDS iceberg; for explanation see text.

[43–45]. Established ARDS clearly represents a major demand on intensive care and rehabilitation resources. One North American study indicated that in fatalities the average time from diagnosis to death was 16 days, whereas in survivors the average time to discharge was 47 days [43].

### Predisposing events and predictive factors

It is generally held that about 40–60% of ARDS cases are associated with sepsis, 20–35% with multiple trauma, 20–35% with pneumonias and gastric aspiration, 9% with multiple massive transfusions and 7% with acute severe pancreatitis [43,46,47], although there is considerable variation between clinical studies. One clear message is that patients with several risk factors have a much higher incidence (45%) compared to those with a single factor (6%) [46]. Sepsis, particularly Gram-negative septicaemia, is clearly a major problem [46]. Bacteraemia alone is associated with a comparatively low risk of developing full-blown ARDS, but when a systemic response or organ failure occurs up to 40% may develop the condition.

Even if better clinical definitions are achieved and result in an improved overall indication of risk for a particular predisposing condition, it is currently impossible to predict which individual patients in a given risk group are most, or least, likely to develop full-blown ARDS. The ability to do this would be not only of great value in epidemiological studies and in planning management but might also highlight key mechanisms that could be targeted in those patients at the highest risk, perhaps before the onset of full-blown disease.

The recognition that ARDS in its early stages is a form of acute inflammatory microvascular injury (see below) has led to a number of attempts to identify markers of inflammatory events as important predictors of the subsequent development of full-blown disease. However, many of these studies have been disappointing, perhaps because they were carried out at varying times after insult, often in

the late risk period or when patients were established in the intensive therapy unit (ITU), by which time the inflammatory response is likely to be advanced and complex. Furthermore most included either a variety of risk groups or conditions such as 'sepsis syndrome' that make it difficult to apply an accepted stringent definition and to determine the time of onset. Early attempts were made to implicate the complement product C5a as a final common pathway, since it is activated in sepsis and multiple trauma and is known to activate neutrophils and other inflammatory cells. Yet in experimental models, complement activation alone was not sufficient to cause lung injury [48] and it has been demonstrated that there is no relationship between blood C5a levels and the development of ARDS [49]. This is not to suggest that C5a is not an important mediator, particularly in combination with other agents. In this regard it has been shown that C5a and other neutrophil-activating agents need to be combined with a priming agent such as endotoxin (the active agent on the surface of Gram-negative organisms) in order to cause either a maximal inflammatory cell secretory response [50] or neutrophil-mediated injury *in vitro* and *in vivo* [51,52]. In the late risk period it is perhaps unreasonable, given the vast redundancy of mediators inherent in the inflammatory response, to expect a single mediator to predict the onset or severity of ARDS. Nevertheless, attempts have been made to link other powerful mediators, such as tumour necrosis factor (TNF)- $\alpha$ , with ARDS in this fashion. TNF- $\alpha$  is undoubtedly centrally important in the initiation of inflammatory responses and when infused in animals causes many of the features of endotoxic shock [53], but in patients no relationship has been found between TNF- $\alpha$  levels and the onset or severity of ARDS [54,55]. In this example timing may perhaps have been an issue, since TNF- $\alpha$  is likely to exert important effects in the early stages of the initiation of the inflammatory response (see later), while measurements late in the risk period when the subclinical inflammatory response is likely to be well advanced may not be of predictive value.

An alternative approach, taken by the author, has been to investigate well-defined subgroups of patients at risk of ARDS (e.g. due to multiple trauma, in which the initiating event can usually be fairly well timed) during the earliest possible stage of the latent period, usually within 2 h of the episode. In these patients we studied events relating to inflammatory cell recruitment, adhesion, activation and secretion, and correlated markers of these with the subsequent development (or not) of ARDS using Murray's original stringent definition. Under the circumstances of our studies there was a strong statistical relationship between levels of neutrophil elastase in peripheral blood at the early stage of the risk period and subsequent progression to ARDS [56], although specificity was low and the overlap between the groups suggested that neutrophil

elastase alone is unlikely to be a valuable predictor of ARDS. In another study of other potentially damaging neutrophil mechanisms in the ARDS risk period, Parsons and colleagues [57] found in patients with sepsis that levels of superoxide dismutase and catalase activity were related to the development of ARDS.

Although a plethora of inflammatory mediators may be involved in recruiting neutrophils and other inflammatory cells to inflamed tissues, the author's studies have identified no relationship between levels of any circulating mediators and progression of ARDS. However, studies of the appearance of inflammatory mediators in bronchoalveolar lavage (BAL) fluid obtained within 2 h of the provocative event in well-defined subgroups of patients at risk of ARDS have found a strong correlation between concentrations of the neutrophil chemokine interleukin (IL)-8 and subsequent development of ARDS [58]. This relationship was not seen with any other cytokine or chemokine. While it is reasonable to be sceptical about the predictive value of a single inflammatory mediator in a complex inflammatory disease, it is possible that in the early stages of the initiation of inflammation a single mediator or perhaps a small group of mediators may be crucially important. An increase in bronchoalveolar IL-8 has also been found in premature neonates at risk of respiratory distress syndrome [59] and in infants with the cystic fibrosis gene, in whom increased levels in BAL fluid appeared to herald or precede the onset of clinically overt lung disease. Thus IL-8 may become a valuable predictor of the development of ARDS and even an important therapeutic target.

In studies of molecules on the surface of neutrophils that are important in their adhesion to endothelial cells (a prerequisite for cell sequestration/emigration), no relationship has been found between the level of expression of a range of integrin and selectin molecules on *circulating* neutrophils and the subsequent development of ARDS. Once again this is perhaps not surprising, since neutrophils that are 'sticky' are likely to be sequestered in pulmonary microvessels and therefore inaccessible to peripheral blood studies. However, a strong inverse relationship between peripheral blood levels of the cleaved, soluble form of L-selectin (sL-selectin) and the development of ARDS has been found [60]. This molecule is cleaved from the neutrophil surface during the transition from transient adhesion to firm adhesion necessary for neutrophil transmigration of the endothelium, and therefore could provide a blood marker of neutrophil-endothelial interactions in the normally inaccessible pulmonary microvasculature. sL-selectin is known to bind to activated endothelial cells and it is speculated that the low levels that correlate strongly with development of ARDS reflect widespread endothelial activation and/or incipient injury. The inverse relationship between sL-selectin levels and increasing recruitment of other injured organs in the

development of multiple organ failure in these patients lends credence to this hypothesis [60] (Fig. 27.6).

Clearly this work in the early risk period of ARDS must be confirmed and extended. While there is not a reliable prognostic indicator for ARDS currently, it is likely that one, or perhaps a small group, of these markers may serve this function.

### Pathology

The non-specific acute alveolar injury that characterizes ARDS was first described in detail in 1976 and assigned the term 'diffuse alveolar damage' (DAD) [61] (Fig. 27.7). Like the clinical situations in which diverse predisposing condi-

Fig. 27.6 Relationship between plasma sL-selectin levels and subsequent multiple organ failure score.

tions appear to result in the common clinical picture described by Ashbaugh and colleagues [1], DAD can be induced by a wide variety of noxious stimuli [62]. In its early stages the alveoli may show evidence of atelectasis and the lung microvessels may appear engorged. The alveolar septa are oedematous, with inflammatory exudate and extravasated erythrocytes, and a proteinaceous inflammatory exudate may flood the alveoli in some areas of the lung (see Plate 27.1a, facing p. 630). Increased numbers of neutrophils may be seen in capillaries and in the interstitial spaces and, if obtained at the earliest stages, BAL fluid shows large numbers of neutrophils (Plate 27.1b, facing p. 630). It has been shown that neutrophil numbers and the concentration of neutrophil-secreted products in BAL fluid appear to correlate with ARDS and its severity. The initiation of lung injury is likely to occur within the pulmonary capillaries (see below) and these observations draw attention to the likely role of neutrophils early in pathogenesis. On ultrastructural examination there is clear evidence of endothelial and epithelial injury, and this may be extensive. Hyaline membranes, the light microscopical hallmark of DAD, are likely to be derived from layers of necrotic epithelial cells (see Fig. 27.7).

It is important to recognize that these pathological events do not occur in a strictly ordered sequence and may appear to have reached different stages in different parts of the lungs. It is not unusual to find evidence of continued inflammatory injury at the same time as alveolar type II cell proliferation or other evidence of attempts at repair. In those patients who die after just a few days of mechanical ventilation there is often evidence of a pronounced fibroproliferative response (Plate 27.1c, facing p. 630), including fibroblast migration into injured alveoli and fibroblast proliferation and collagen deposition that within 2 weeks can be quite remarkable (Plate 27.1d, facing p. 630). Never-

theless in those patients who survive the initiating condition and who are mechanically ventilated, death is not usually due to progressive respiratory failure but to failure of other organs less easy to support than the lung, to septicaemia or to secondary noscomial infections in the injured lung. However, barotrauma from mechanical ventilation of poorly compliant lungs can be a major problem in some patients.

Very little is known about the pathology of the recovery phase of ARDS since there are few case reports describing lung biopsies that have been repeated for clinical indications; these have suggested that some pulmonary remodelling may occur. Intuitively, however, the examples of occasional patients with severe ARDS who may have been ventilated for many days yet who nevertheless appear to regain virtually normal lung function suggest that some forms of inflammatory lung injury and perhaps even fibrosis have the capacity to resolve and/or become remodelled.

## Pathogenesis: cellular and humoral mechanisms

### Neutrophils and other inflammatory cells

Neutrophils have long been recognized in the lung tissues of necropsy specimens obtained early in the natural history of ARDS [63]; similarly, cytology of BAL fluid shows a high percentage of neutrophils (see Plate 27.1b, facing p. 630) and their products such as myeloperoxidase, which correlate with the development and severity of the condition. Other potentially injurious neutrophil products, including elastase and collagenase, are also found [64,65]. Of particular importance, peripheral blood levels of neutrophil elastase in patients at risk of ARDS correlate with subsequent development of the condition [56]. External imaging of radiolabelled neutrophils has demonstrated neutrophil accumulation in the lungs of patients with ARDS [66], and recent studies have suggested that

the specific neutrophil chemokine IL-8 may be critically related to the development of the condition [58]. Studies in animal models of acute lung injury using stimuli relevant to the pathogenesis of ARDS specifically implicate the neutrophil. In a sheep model, neutrophil depletion abrogated endotoxin-induced lung injury [67]; in a rabbit model of lung injury induced by a combination of endotoxin and C5a, the injury was abolished by neutrophil depletion and reconstituted by replenishment of neutrophils [52]. This body of evidence has led a number of observers to implicate the neutrophil as centrally important in the pathogenesis of ARDS [63,68,69].

This is not to suggest that other inflammatory cells are unimportant in the pathogenesis of this condition. In fact ARDS has been described in neutropenic patients [70], although histology does show the presence of some neutrophils in the lungs and it is uncertain how much of a neutrophil load may be required; certainly neutrophil replenishment experiments in neutropenic animals replace only a small proportion of the total neutrophil complement. Nevertheless, these studies of neutropenic patients raise the possibility that other cells, perhaps monocytes (which possess most, if not all, of the potentially injurious mechanisms and capacity of neutrophils), play an important ancillary role or may even substitute for granulocytes under some circumstances.

In summary, it is widely accepted that in the pathogenesis of most cases of ARDS a key role is played by the neutrophil, which is able to generate a range of reactive oxygen intermediates (ROI) and potentially histotoxic granule contents such as elastase and collagenase [71,72]. It is now generally believed that one of the earliest initiation mechanisms is damage to the capillary endothelial cells and airway epithelial cells that form the delicate alveolar gas-exchange membrane caused by toxic products of inflammatory cells that have become sequestered and activated as a result of inflammatory mediators generated as a consequence of the initiating insult (Fig. 27.8). It is uncer-

**Fig. 27.8** Early events in acute lung injury.

tain why lung injury is so prominent and is often the first clinically obvious event in the multisystem microvascular injury of multiple organ failure. However, this may be partly due to the fact that the major part of the marginating pool of neutrophils resides in lung capillaries; even in the healthy state, neutrophils (average diameter 7.5  $\mu\text{m}$ ) have to squeeze through lung capillaries (mean diameter 5.5  $\mu\text{m}$ ), thus presenting a massive surface area of contact between this potentially injurious cell and the vulnerable gas-exchange membrane (Fig. 27.9). With regard to this interaction, it is now clear that neutrophils cannot injure cells or degrade matrix proteins without being extremely closely apposed, and an understanding of the kinetics and adhesion mechanisms involved are essential in order to appreciate the pathogenesis of acute lung injury. Finally, it is now clear that neutrophil secretion is not necessarily an all-or-nothing phenomenon; it is likely to be tightly controlled and, for maximum release of ROI or granule enzymes, the neutrophil has to be exposed to agents that prime the cell (see below) together with those that trigger the cell. In order to simplify the complex mechanisms likely to be involved in neutrophil-mediated injury the discussion is divided as follows:

- 1 involvement of mediators, particularly those involved in inflammatory cell sequestration and activation in the lung;
- 2 neutrophil-endothelial interaction and the creation of an injury-favouring microenvironment;
- 3 potentially injurious neutrophil products released from primed and triggered neutrophils.

### Mediators

A very large number of mediators, indeed several media-

tor cascades, have been implicated in the pathogenesis of ARDS.

### Endotoxic lipopolysaccharide

Endotoxic lipopolysaccharide (LPS) is the main 'active' ingredient of the cell walls of *Escherichia coli* and other Gram-negative organisms that cause sepsis syndrome, septic shock and ARDS. When injected into animals, LPS causes many of the pathophysiological features of septic shock and, in some animals such as the sheep, acute lung injury [67]. Low concentrations of LPS may also enter the circulation of patients with circulatory shock by the process of translocation across the compromised gut lining [73–75]. LPS exerts a number of direct influences on neutrophils and very low concentrations (pg/mL) are required in the presence of serum when LPS interacts with a protein called LPS-binding protein to ligate CD14 on the neutrophil surface [76–78]. LPS alone is not a good neutrophil secretagogue but causes enhanced expression of neutrophil surface adhesion molecules that bind the activated endothelium [79] (see Table 27.6) and causes a direct reduction in neutrophil deformability [80], both of these events being critical for neutrophil sequestration in pulmonary microvessels. LPS also causes macrophages to release cytokines (including IL-1 and TNF- $\alpha$  which play key roles in the initiation of inflammation), activates other cascades including the complement, coagulation and kinin cascades, and generates systemic cytokines (including IL-6) that regulate the acute-phase response.

While endotoxin probably plays a key early role in the pathogenesis of ARDS [81] and can be detected in patients both with and at risk of ARDS [82–84], so far antiendotoxin therapeutic strategies have proved disappointing. In

Fig. 27.9 Electron micrograph of neutrophil in pulmonary capillary.

part this may have been because the trials were carried out in patients with established sepsis syndrome when the mediator cascades induced by LPS were probably already well established, and the time may have passed when LPS might have played a critical role. Other studies suggest that while LPS alone exerts some important effects, for induction of lung injury it needs to be combined with other inflammatory mediators such as C5a [52].
